

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

H. L. FAIRCHILD

SCIENTIFIC DIALOGUES.
INTENDED FOR THE
INSTRUCTION AND ENTERTAINMENT
OF
YOUNG PEOPLE:

IN WHICH
THE FIRST PRINCIPLES
OF
NATURAL AND EXPERIMENTAL PHILOSOPHY
ARE FULLY EXPLAINED.

**VOL. III. OF OPTICS, MAGNETISM, ELECTRICITY
AND GALVANISM.**

“Conversation, with the habit of explaining the meaning
“of words and the structure of common domestic implements
“to children, is the sure and effectual method of preparing
“the mind for the acquirement of science.”

Edgeworth's Practical Education

BY THE REV. J. JOYCE.

A NEW EDITION, CORRECTED AND IMPROVED.

PHILADELPHIA:

**PUBLISHED BY ANTHONY FINLEY, MAROT & WALTER, BEN-
NETT & WALTON, BENJAMIN & THOMAS KITE, H. C. C
REY & I. LEA, M'CARTY & DAVIS, KIMBER & SHAN-
LESS, AND LYDIA R. BAILEY.**

ASTOR LENOX AND
TILDEN FOUNDATIONS.
1900.

TO
ANNA LÆTITIA BARBAULD,
AND
JOHN AIKIN, M. D..
AUTHORS OF
“EVENINGS AT HOME,”
AND
OTHER ADMIRABLE WORKS
FOR
THE INSTRUCTION OF YOUNG PERSONS,
THE THIRD VOLUME OF
SCIENTIFIC DIALOGUES
IS RESPECTFULLY INSCRIBED
BY
THE AUTHOR

ADVERTISEMENT.

IN presenting to the public the concluding volume of the **SCIENTIFIC DIALOGUES**, the *Author* cannot but acknowledge, with sentiments of gratitude, the favourable reception which the former parts of the work have experienced. He trusts, that the several subjects comprised in this last volume, will have an equal claim to the candour of those who are engaged in the arduous but honourable employment of education.

It will be seen that it was quite impossible to include in the three volumes the introduction to chemistry, as was originally intended. This branch of science is become so very interesting and the study of it so general, that it would have been unpardonable to have devoted only a part of a volume to the discussion of it; the *Author* has, therefore, at the suggestion and desire of many friends, who have given their approbation to the *Scientific Dialogues*, undertaken to furnish a separate work on this subject, in two volumes, similar in size to this.

OPTICS.

CONVERSATION I.

INTRODUCTION.

Of Light—The Smallness of its Particles—Their Velocity—
They move only in straight Lines.

CHARLES. When we were on the sea, you told us that you would explain the reason why the oar, which was straight when it lay in the boat, appeared crooked as soon as it was put into the water.

Tutor. I did: but it requires some previous knowledge before you can comprehend the subject. It would afford you but little satisfaction to be told that this deception was caused by the different degrees of *refraction* which takes place in water and in air.

James. We do not know what you mean by the word *refraction*.

Tutor. It will therefore be right to proceed with caution; *refraction* is a term frequently used in the science of optics, and this science depends wholly on *light*.

James. What is *light*?

Tutor. It would, perhaps, be difficult to give a direct answer to your question, because we know nothing of the nature of light, but by the effects which it produces. In reasoning, however, on this subject, it is generally admitted that light consists of inconceivably small particles; which are projected, or thrown off from a luminous body with great velocity, in all directions.

Charles. But how is it known that light is composed of small particles?

Tutor. There is no proof indeed that light is *material*, or composed of particles of matter, and therefore I said it was *generally*, not *universally*, admitted to be so; but if it is allowed that light is matter, then the particles must be small beyond all computation, or in falling on the eye they would infallibly blind us.

James. Does not the light come from the sun, in some such manner as it does from a candle?

Tutor. This comparison will answer our purpose; but there appears to be a great difference between the two bodies: a candle, whether of wax or tallow, is soon exhausted; but philosophers have never been able to observe that the body of the sun is diminished by the light which it incessantly pours forth.

James. You say incessantly; but we see only during the hours of day.

Charles. That is because the part of the earth *which we inhabit* is turned away from the sun

during the night: but our midnight is mid-day to some other parts of the earth.

Tutor. Right: besides you know the sun is not intended merely for the benefit of this globe but it is the source of light and heat to six other planets, and eighteen moons belonging to them.

Charles. And you have not reckoned the four newly discovered little planets, which Doctor Herschel denominates *Asteroids*, but which are known by the name of Ceres Ferdinanda, Pallas, Juno, and Vesta.

Tutor. Well then: the sun to these is the perpetual source of light, heat, and motion; and to more distant worlds it is a fixed star, and will appear to some as large as Arcturus, to others no larger than a star of the sixth magnitude, and to others it must be invisible, unless the inhabitants have the assistance of glasses, or are endowed with better eyes than ourselves.

James. Pray, sir, how swift do you reckon that the particles of light move?

Tutor. This you will easily calculate, when you know, that they are only about eight minutes in coming from the sun.

Charles. And if you reckon the sun to be at the distance of ninety-five millions of miles from the earth; light proceeds at the rate, nearly, of twelve millions of miles in a minute, or a 200,000 miles in a second of time. But how do you know that it travels so fast?

Tutor. It was discovered by M. Roemer, when

observed that the eclipses of Jupiter's satellites took place about sixteen minutes later, if the earth were in that part of its orbit, which is farthest from Jupiter, than if it were in the opposite point of the heavens.

Charles. I understand this; the earth may sometimes be in a line between the sun and Jupiter, and at other times the sun is between the earth and Jupiter; and therefore, in the latter case, the distance of Jupiter from the earth is greater than in the former, by the whole length of its orbit.

Tutor. In this situation, the eclipse of any of the satellites is, by calculation, sixteen minutes later than it would be, if the earth were between Jupiter and the sun; that is, the light flowing from Jupiter's satellites is about sixteen minutes in travelling the length of the earth's orbit, or 190 millions of miles.

James. It would be curious to calculate how much faster light travels than a cannon-ball.

Tutor. Suppose a cannon-ball to travel at the rate of twelve miles a minute; and light to move a million of times faster than that; yet Dr. Akenside conjectures that there may be stars so distant from us that the light proceeding from them has not yet reached the earth:

—Whose unfading light
Has travell'd the profound six thousand years,
Nor yet arriv'd in sight of mortal things.

Charles. Was it to this author that Dr. Young alludes in these lines?

How distant some of the nocturnal suns !
So distant, says the sage, 'twere not absurd
To doubt, if beams, set out on Nature's birth,
Are yet arriv'd at this so foreign world ;
Though nothing half so rapid as their flight.

Tutor. He probably referred to Huygens, a eminent astronomer, who threw out the idea before Akenside was born.

James. And you say the particles of light move in all directions.

Tutor. Here is a sheet of thick brown paper I make only a small pin-hole in it, and the through that hole, I can see all the objects such as the sky, trees, houses, &c. as I could the paper were not there.

Charles. Do we only see objects by means of the rays of light which flow from them?

Tutor. In no other way : and therefore the light that comes from the landscape, which view by looking through the small hole in the paper, must come in all directions at the same time.—Take another instance ; if a candle be placed on an eminence in a dark night, it may be seen all round for the space of half a mile in other words, there is no place within a sphere of a mile in diameter, where the candle cannot be seen, that is, where some of the rays from the small flame will not be found.

OPTICS.

James. Why do you limit the distance a mile?

Tutor. The distance, of course, will be more or less, according to the size of the candle, but the degree of light, like heat, diminishes in proportion as you go farther from the luminous body.

Charles. Does it follow the same law as gravity?*

Tutor. It does: the intensity or degree of light decreases as the square of the distance from the luminous body increases.

James. Do you mean, that at the distance of two yards from a candle, we shall have four times less light, than we should have, if we were only one yard from it?

Tutor. I do: and at three yards distance you will have nine times less light; and at four yards distance you will have sixteen times less light than you would have if you were within a yard of the object. I have one more thing to tell you: light moves in straight lines.

James. How is that known?

Tutor. Look through a straight tube at an object, and the rays of light will flow from it to the eye, but let the tube be bent, and the object cannot be seen through it, which proves that light will move only in a straight line.

* See Scientific Dialogues. Vol. I. Conversation

This is plain also from the shadows which opaque bodies cast ; for if the light did not describe straight lines, there would be no shadow. Hold any object in the light of the sun, or candle, as a square board or book, and the shadow caused by it proves that light moves only in right or straight lines.

CONVERSATION II.

Of Rays of Light—Of Reflection and Refraction.

Charles. You talked, the last time we met, of the rays of light flowing or moving ; what do you mean by a *ray of light* ?

Tutor. Light, you know, is supposed to be made up of indefinitely small particles ; now one or more of these particles in motion from any body, is called a ray of light.—If the supposition be true, that light consists of particles flowing from a luminous body, as the sun, and that these particles are about eight minutes in coming from the sun to us ; then if the sun were blotted from the heavens, we should actually

have the same appearance for eight minutes after the destruction of that body as we now have.

James. I do not understand how we could see a thing that would not exist.

Tutor. The sun is perpetually throwing off particles of light, which travel at the rate of twelve millions of miles in a minute, and it is by these that the image of the body is impressed on our eye. The sun being blotted from the firmament would not affect the course of the particles that had the instant before been thrown from his body; they would travel on as if nothing had happened, and till the last particles had reached the eye, we should think we saw the sun, as much as we do now.

Charles. Do we not actually see the body itself?

Tutor. The sense of sight may, perhaps, not be unaptly compared to that of smell: a grain of musk will throw off its odoriferous particles all round, to a considerable distance; now if you or I happen to be near it, the particles which fall upon certain nerves in the nose will excite in us those sensations, by which we say we have the smell of musk. In the same way particles of light are flowing in every direction from the grain of musk, some of which fall on the eye, and these excite different sensations, from which we say, we see a piece of musk.

Charles. But the musk will in time be completely dissipated, by the act of throwing off the

fine particles ; whereas a chair or a table may throw off its rays so as to be visible, without ever diminishing its size.

Tutor. True : because whatever is distinguished by the sense of smell, is known only by the particles of the odoriferous body itself flowing from it : whereas a body distinguished by the sense of sight is known by the rays of light which first fall on the body, and are then reflected from it.

James. What do you mean by being reflected?

Tutor. If I throw this marble smartly against the wainscot, will it remain where it was thrown?

James. No : it will rebound, or come back again.

Tutor. What you call rebounding, writers on optics denominate *reflection*. When a body of any kind, whether it be a marble with which you play, or a particle of light, strikes against a surface, and is sent back again, it is said to be reflected. If you shoot a marble straight against a board, or other obstacle, it comes back in the same line, or nearly so ; but suppose you throw it sideways, does it return to the hand?

Charles. Let me see : I will shoot this marble against the middle of one side of the room, from the corner of the opposite side.

James. You see, instead of coming back to your hand, it goes off to the other corner, di

rectly opposite to the place from which you sent it.

Tutor. This will lead us to the explanation of one of the principal definitions in optics, viz. *that the angle of reflection is always equal to the angle of incidence.* You know what an angle is?*

Charles. We do : but not what an angle of incidence is.

Tutor. I said a ray of light was a particle of light in motion : now there are *incident* rays, and *reflected* rays.

The *incident* rays are those which *fall on* the surface ; and the *reflected* rays are those which are *sent off* from it.

Charles. Does the marble *going to* the wainscot represent the *incident* ray, and in *going from* it, does it represent the *reflected* ray ?

Tutor. It does : and the wainscot may be called the reflecting surface.

James. Then what are the angles of incidence and reflection ?

Tutor. Suppose you draw the lines on which the marble travelled, both to the wainscot, and from it again.

Charles. I will do it with a piece of chalk.

Tutor. Now draw a perpendicular† from the

* See Scientific Dialogues. Vol. I. Conversation I.

† If the point be exactly in the middle of one side of the room, a perpendicular is readily drawn by finding the middle of the opposite side, and joining the two points.

point where the marble struck the surface, that is, where your two lines meet.

Charles. I see there are two angles, and they seem to be equal.

Tutor. We cannot expect mathematical precision in such trials as these ; but if the experiment were accurately made, the two angles would be perfectly equal : the angle contained between the incident ray, and the perpendicular is called the angle of incidence, and that contained between the perpendicular and reflected ray, is called the angle of reflection.

James. Are these in all cases equal, should I move the marble as you will ?

Tutor. They are : and the truth holds equally with the rays of light :—both of you stand in front of the looking-glass. You see yourselves and one another also ; for the rays of light flow from you to the glass, and are reflected back again in the same lines. Now both of you stand on one side of the room. What do you see ?

Charles. Not ourselves, but the furniture on the opposite side.

Tutor. The reason of this is, that the rays of light flowing from you to the glass, are reflected to the other side of the room.

Charles. Then if I go to that part, I shall see the rays of light flowing from my brother :—and I do see him in the glass.

James. And I see Charles.

Tutor. Now the rays of light flow from each of you to the glass, and are reflected to one another: but neither of you sees himself.

Charles. No: I will move in front of the glass now I see myself but not my brother; and, think, I understand the subject very well.

Tutor. Then explain it to me by a figure which you may draw on the slate.

Charles. Let AB (Plate I. Fig. 1.) represent the looking-glass: if I stand at c , the rays flow from me to the glass, and are reflected back the same line, because now there is no angle of incidence, and of course no angle of reflection; but if I stand at x , then the rays flow from me to the glass, but they make the angle xoc , and therefore they must be reflected in the line oy so as to make the angle yoc , which is the angle of reflection, equal to the angle xoc . And if James stand at y , he will see me at x , and standing at x , shall see him at y .

CONVERSATION III.

Of the Refraction of Light.

Charles. If glass stop the rays of light, reflect them, why cannot I see myself in the window?

THE REFRACTION OF LIGHT.

Tutor. It is the silvering on the glass which causes the reflection, otherwise the rays would pass through it without being stopped, and they were not stopped, they could not be reflected. No glass, however, is so transparent, but it reflects some rays: put your hand to within three or four inches of the window, and you see clearly the image of it.

James. So I do, and the nearer the hand is to the glass, the more evident is the image, but it is formed on the other side of the glass and beyond it too.

Tutor. It is; this happens also in looking-glasses: you do not see yourself on the surface, but apparently as far behind the glass, as you stand from it in the front.

Whatever suffers the rays of light to pass through it is called a *medium*. Glass, which is transparent, is a medium; so also is air, water, and indeed all fluids that are transparent, are called *media*, and the more transparent the body, the more perfect is the medium.

Charles. Do the rays of light pass through in a straight line?

Tutor. They do; but not in precisely the same direction in which they were moving before they entered it. They are *bent* out of their former course, and this is called *refraction*.

James. Can you explain this term more fully?

Tutor. Suppose A B (Plate I. Fig. 2.) to be

a piece of glass, two or three inches thick, a ray of light $s a$, to fall upon it at a , not pass through in the direction $s s$, it comes to a , it will be bent towards the perpendicular $a b$, and go through the glass in the course $a x$, and when it comes into the air it will pass on in the direction $x z$, which is parallel to $s s$.

Charles. Does this happen if the ray falls perpendicularly on the glass at $P a$?

Tutor. In that case there is no refraction, but the ray proceeds in its passage through the glass, precisely in the same direction as before it entered it, namely, in the direction $s s$.

James. Refraction then takes place only when the rays fall obliquely or slantwise on the surface of the diuim.

Tutor. Just so: rays of light may pass from a rarer into a denser medium, as from air to water or glass: or they may pass from a denser medium into a rarer, as from water or glass into air.

Charles. Are the effects the same in both cases?

Tutor. They are not: and I wish you to remember the difference. When light passes from a rarer into a denser medium, it is bent towards the perpendicular; thus, if $s a$ pass from air to glass, it moves, in its passage through the glass, in the line $a x$, which is nearer to the perpendicular than $s s$ is.

lar $a b$ than the line $a s$, which was its first direction.

But when a ray passes from a denser medium into a rarer, it moves in a direction *farther* from the perpendicular; thus if the ray $x a$ pass through glass or water into air, it will not, when it comes to a , move in the direction $a m$, but in the line $a s$, which is further than $a m$ from the perpendicular $a p$.

James. Can you show us any experiment in proof of this?

Tutor. Yes, I can: here is a common earthen pan, on the bottom of which I will lay a shilling, and will fasten it with a piece of soft wax so that it shall not move from its place, while I pour in some water. Stand back till you just lose sight of the shilling.

James. The side of the pan now completely hides the sight of the money from me.

Tutor. I will pour in a pitcher of clear water.

James. I now see the shilling: how is this to be explained?

Tutor. Look to the last figure, and conceive your eye to be at s , $a b$ the side of the pan, and the piece of money to be at x : now when the pan is empty, the rays of light flow from x , in the direction $x a m$, but your eye is at s , of course you cannot see any thing but the ray proceeding along $x a m$. As soon as I put the water into the vessel, the rays of light proceed from x to a , but there they enter from a dense

to a rarer medium; and therefore, instead of moving in *a m*, as they did when there was no water, they will be bent *from* the perpendicular, and will come to your eye at *s*, as if the shilling were situate at *n*.

James. And it does appear to me to be so.

Tutor. Remember what I am going to show you, for it is a sort of axiom in optics: that we see every thing in the *direction* of that line in which the rays approach us last." Which may be thus illustrated: I place a candle before a looking-glass, and if you stand also before the same glass, the image of the candle appears behind it; but if another looking-glass be so placed as to receive the reflected rays of the candle, and you stand before this second glass, the image will appear behind that; because the mind imagines every object seen along the line in which the rays come to the eye last.

Charles. If the shilling were not moved, and the pouring in of the water, I do not understand how we could see it afterwards.

Tutor. But you do see it now at the place where it was, or rather at the little dot just above it, which is an inch or two from the place where it was at first, when it was at the bottom, and from which, you may convince yourself, it has not moved.

James. I should like to be convinced of this. Will you make the experiment again, that I may be satisfied of it?

Tutor. You may make it as often as you please.

please, and the effect will always be the same but you must not imagine that the shilling only will appear to move, the bottom of the vessel seems also to change its place.

James. It appears to me to be raised higher as the water is poured in.

Tutor. I trust you are satisfied by this experiment: but I can show you another equally convincing; but for this we stand in need of the sun.

Take an empty vessel *A*, a common pan or basin will answer the purpose, (Plate I. Fig. 3) into a dark room, having only a very small hole in the window shutter: so place the basin that a ray of light *s s* shall fall upon the bottom at *a*, here I make a small mark, and then fill the basin with water. Now where does the ray fall?

James. Much nearer to the side at *b*.

Tutor. I did not move the basin, and therefore could have had no power in altering the course of light.

Charles. It is very clear that the ray was refracted by the water at *s*: and I see that the effect of refraction in this instance has been to draw the ray nearer to a perpendicular, which may be conceived to be the side of the vessel.

Tutor. The same thing may be shown with a candle in a room otherwise dark: let it stand in such a manner as that the shadow of the side of a pan or box may fall somewhere at the bottom.

tom of it; mark the place, and pour in water, and the shadow will not then fall so far to the side.

CONVERSATION IV.

Of the Reflection and Refraction of Light.

Tutor. We will proceed to some farther illustrations of the laws of reflection and refraction. We shut out all the light except the ray which comes in at the small hole in the shutter at the bottom of this basin, where the ray of light falls, I lay this piece of looking-glass; and the water be rendered in a small degree opaque by mixing with it a few drops of milk, and the room be filled with dust by sweeping a candle or any other means, then you will see the refraction which the ray from the shutter undergoes in passing into the water, the reflection at the surface of the looking-glass, and the refraction which takes place when the ray leaves the water, and passes again into the air.

James. Does this refraction take place in all kinds of glass?

Tutor. It does ; but where the glass is very thin, as in window glass, the deviation is so small as to be generally overlooked. You may now understand why the oar in the water appears bent, though it be really straight ; for suppose AB (Plate 1. Fig. 4.) represent water, and $ma x$ the oar, the image of the part $a x$ in the water will lie above the object, so that the oar will appear in the shape $ma n$, instead of $ma x$. On this account also, a fish in the water appears nearer the surface than it actually is, and a marksman shooting at it must aim below the place which it seems to occupy.

Charles. Does the image of the object seen in the water always appear higher than the object really is ?

Tutor. It appears one fourth nearer the surface than the object is. Hence a pond or river is a third part deeper than it appears to be, which is of importance to remember, for many a school-boy has lost his life by imagining the water into which he plunged was within his depth.

James. You say the bottom appears one fourth nearer the surface than it is ; and then that the water is a *third* deeper than it seems to be : I do not understand this.

Tutor. Suppose the river to be six feet deep, which is sufficient to drown you or me, if we cannot swim : I say the bottom will appear to be *only four feet and a half* from the surface, in

which case you could stand and have the greater part of your head above it; of course it appears to be a foot and a half shallower than it is; but a foot and a half is just the *third* part of four feet and a half.

Charles. Can this be shown by experiment?

Tutor. It may:—I take this large empty jar and with a piece of soft wax stick a piece of money at the bottom, but so that you can see it as you stand; keep your position, and I will pour in a quantity of water gradually, and tell me the appearance.

Charles. The shilling rises exactly in the same proportion as you pour in the water.

Tutor. Recollect then, in future, that we cannot judge of *distances* so well in water as in air.

James. And I am sure we cannot of *magnitudes*: for in looking through the sides of a globular glass at some gold and silver fish I thought them very large; but if I looked down upon them from the top, they appear much smaller indeed.

Tutor. Here the convex or round shape of the glass becomes a magnifier, the reason of which will be explained hereafter. A fish viewed through a glass, however, looks larger in water than it really is.—I will show you another experiment which depends on refraction: here is a glass globe two-thirds full of water; I throw into it a shilling, and place a plate on the top of it, and t

it quickly over, that the water may not escape. What do you see?

Charles. There is certainly a half crown lying on the plate, and a shilling seems swimming above it in the water.

Tutor. So it appears, indeed ; but it is a deception which arises from your seeing the piece of money in two directions at once, viz. through the conical surface of the water at the side of the glass, and through the flat surface at the top of the water. The conical surface, as was the case with the globular one in which the fish were swimming, magnifies the money ; but by the flat surface the rays are only refracted, on which account the money is seen higher up in the glass, and of its natural size, or nearly so.

James. If I look sideways at the money, I only see the large piece ; and if only at top, I see it in its natural size and state.

Charles. Look again at the fish in the glass, and you will see through the round part two very large fish, and seeing them from the upper part, they appear of their natural size ; the deception is the same as with the shilling in the goblet.

Tutor. The principle of refraction is productive of some very important effects. By this, the sun, every clear morning, is seen several minutes before he comes to the horizon, and as long after he sinks beneath it in the evening.

Charles. Then the days are longer than they

would be if there was no such a thing as refraction. Will you explain how this happens?

Tutor. I will: you know we are surrounded with an atmosphere, which extends all round the earth, and above it, about the height of forty-five miles; now the dotted part of Fig. 5. presents that atmosphere: suppose a spectator stand at s , and the sun be at a ; if there were no refraction, the person at s would not see rays of the sun till he were situated with respect to the sun in a line sxa ; because when it is below the horizon at b , the rays would pass below the earth in the direction bxx ; but owing to the atmosphere, and its refracting power, when the rays from b reach x , they are bent towards the perpendicular, and carried to the spectator at s .

James. Will he really see the image of the sun while it is below the horizon?

Tutor. He will; for it is easy to calculate the moment when the sun should rise and set, and if that be compared with exact observation it will be found that the image of the sun rises sooner and later than this by several minutes every clear day.

Charles. Are we subject to the same deception when the sun is actually above the horizon?

Tutor. We are always subject to it at all latitudes, and the sun is never in that part of the heavens where he appears to be.

James. Why in these latitudes particularly?

Tutor. Because with us the sun is never in the *zenith*, *s*, or directly over our heads; and in that situation alone, his *true* place in the heavens is the same as his *apparent* place.

Charles. Is that because there is no refraction when the rays fall perpendicularly on the atmosphere?

Tutor. It is: but when the sun (Plate I. Fig. 5.) is at *m*, his rays will not proceed in a direct line *m o r*, but will be bent out of their course at *o*, and go in the direction *o s*, and the spectator will imagine he sees the sun in the line *o n*.

Charles. What makes the moon look so much larger when it is just above the horizon, than when it is higher up?

Tutor. The thickness of the atmosphere, when the moon is near the horizon, renders it less bright than when it is higher up, which leads us to suppose it is farther off in the former case than in the latter; and because we imagine it to be farther from us, we take it to be a larger object than when it is higher up.

It is owing to the atmosphere that the heavens appear bright in the day time. Without an atmosphere, only that part of the heavens would appear luminous in which the sun is placed; in that case, if we could live without air, and should stand with our backs to the sun, the whole heavens would appear as dark as *night*.

CONVERSATION V.

Definitions—Of the different kind of Lenses—Of Mr. Park's
Burning Lens, and the effects produced by it.

Tutor. I must claim your attention to a few other definitions; the knowledge of which will be wanted as we proceed.

A *pencil of rays* is any number that proceed from a point.

Parallel rays are such as move always at the same distance from each other.

Charles. That is something like the definition of *parallel lines*.* But when you admitted that rays of light through the small hole in the shutter, they did not seem to flow from that point in parallel lines, but to recede from each other in proportion to their distance from that point.

Tutor. They did; and when they do thus recede from each other, as in this figure (Plate Fig. 6.) from c to cd , then they are said to *diverge*. But if they continually approach to each other, as in moving from cd to c , they are said to *converge*.

* Parallel lines are those which being infinitely extended never meet.

James. What does the dark part of this figure represent?

Tutor. It represents a glass lens, of which there are several kinds.

Charles. How do you describe a lens?

Tutor. A *lens* is a glass ground into such a form as to collect or disperse the rays of light which pass through it. They are of different shapes, from which they take their names. They are represented here in one view. (Plate I. Fig. 7.) **A** is such a one as that in the last figure, and it is called a *plano-convex*, because one side is flat, and the other convex; **B** is a *plano-concave*, one side being flat, and the other *concave*; **C** is a *double-convex lens*, because both sides are convex; **D** is a *double-concave*, because both sides are concave; and **E** is called a *meniscus*, being convex on one side, and concave on the other; of this kind are all watch glasses.

James. I can easily conceive of diverging rays, or rays proceeding from a point; but what is to make them converge, or come to a point?

Tutor. Look again to the figure (Fig. 6.) now *a, b, m, &c.* represent parallel rays, falling upon *cd* a convex surface, of glass for instance, all of which, except the middle one, fall upon it obliquely, and, according to what we said yesterday, will be refracted towards the perpendicular.

the radius of the other to the distance of the focus from the middle point."

James. Then if one radius be four inches, and the other three inches, I say, as $4+3 : 4$ so $6 : \frac{24}{7} = 3\frac{3}{7}$, or to nearly three inches and a half. I saw a gentleman lighting his pipe yesterday, by means of the sun's rays and a glass; is that a double convex lens?

Tutor. I dare say it was: and you now see the reason of that which then you could not comprehend: all the rays of the sun that fall on the surface of the glass (see Fig. 8.) are collected in the point *f*, which, in this case, may represent the tobacco in the pipe.

Charles. How do you calculate the heat which is collected in the focus?

Tutor. The force of the heat collected in the focus is in proportion to the common heat of the sun, as the area of the glass is to the area of the focus: of course, it may be a hundred or even a thousand times greater in the one case than in the other.

James. Have I not heard you say that Mr. Parker, of Fleet-street, made once a very large lens, which he used as a burning-glass?

Tutor. He formed one three feet in diameter, and when fixed in its frame, it exposes a clear surface of more than two feet eight inches in diameter, and its focus, by means of another lens, was reduced to a diameter of half an inch. The heat produced by this was so great, that

iron plates were melted in a few seconds: and slates became red-hot in a moment, were vitrified, or changed into glass: sulphur, pitch, and other resinous bodies, were melted under water: wood-ashes, and those of vegetable substances, were turned in a moment into transparent glass.

Charles. Would the heat produced by it melt all the metals?

Tutor. It would: even gold was rendered fluid in a few seconds; notwithstanding, however, this intense heat at the focus, the finger might, without the smallest injury, be placed in the cone of rays within an inch of the focus.

James. There was, however, I should suppose, some risk in this experiment, for fear of bringing the finger too near the focus.

Tutor. Mr. Parker's curiosity led him to try what the sensation would be at the focus: he describes it like that produced by a lancet, and not at all similar to the pain produced by the heat of fire or a candle. The stances of a white colour were difficult to be acted upon.

Charles. I suppose he could make water boil in a very short time with the lens.

Tutor. If the water be very pure, and contained in a clear glass decanter, it will be warmed by the most powerful lens. But a piece of wood may be burned to a coal, which is contained in a decanter of water.

mes. Will not the heat break the glass?
stor. It will scarcely warm it: if, however, a piece of metal be put in the water, and the heat of rays be thrown on that, it will communicate heat to the water, and sometimes make oil. The same effect will be produced if there be some ink thrown into the water.

If a cavity be made in a piece of charcoal, the substance to be acted on be put in it, the effect produced by the lens will be much increased. Any metal thus enclosed melts in a moment, the fire sparkling like that of a forge, in which the blast of a bellows is applied.

CONVERSATION VI.

Parallel Rays—Of diverging and converging Rays—Of the Focus and focal distances.

Charles. I have been looking at the figures 6, 7, 8, and see that the rays falling upon the object are parallel to one another: are the sun's rays parallel?

utor. They are considered so: but you must suppose that all the rays that come from the
VOL. III.—D

surface of an object, as the sun, or any other body, to the eye, are parallel to each other, it must be understood of those rays only which proceed from a single point. Suppose *s* (Pl. I. Fig. 9.) to be the sun, the rays which proceed from a single point *A*, do in reality form a cone, the *base* of which is the pupil of the eye, and its height is the distance from us to the sun.

James. But the breadth of the eye is nothing when compared to a line ninety-five million miles long.

Tutor. And for that reason, the various rays that proceed from a single point in the sun are considered as parallel, because their inclination to each other is insensible. The same may be said of any other point as *c*. Now all the rays that we can admit by means of a small aperture or hole, must proceed from an indefinite small point of the sun, and therefore they are justly considered as parallel.

If now we take a ray from the point *A*, and another from *c*, on opposite points of the sun's disk, they will form a sensible angle at the eye, and it is from this angle *A E C* that we judge of the apparent size of the sun, which is about half a degree in diameter.

Charles. Will the size of the pupil of the eye make any difference with regard to the appearance of the object?

Tutor. The larger the pupil, the brighter the object appears, because the larger the pupil

is, the greater number of rays it will receive from any single point of the object.—And I wish you to remember what I have told you before, that whenever the appearance of a given object is rendered larger and brighter, we always imagine that the object is nearer to us than it really is, or than it appears at other times.

James. If there be nothing to receive the rays (Fig. 8.) at f , would they cross one another and diverge?

Tutor. Certainly, in the same manner as they converged in coming to it; and if another glass $r g$, of the same convexity as $D E$, be placed in the rays at the same distance from the focus, it will so refract them, that, after going out of it, they will be parallel, and so proceed on in the same manner as they came to the first glass.

Charles. There is, however, this difference; all the rays, except the middle one, have changed sides.

Tutor. You are right; the ray B , which entered at bottom, goes out at the top b ; and A , which entered at the top, goes out at the bottom a , and so of the rest.

If a candle be placed at f , the focus of the convex glass, the diverging rays in the space $r f g$, will be so refracted by the glass, that after going out of it, they will become parallel again.

James. What will be the effect if the candle be nearer to the glass than the point f ?

Tutor. In that case, as if the candle (Plate II. Fig. 10.) the rays will diverge after they have passed through the glass, and the vergency will be greater or less in proportion as the candle is more or less distant from the focus.

Charles. If the candle be placed farther from the lens than the focus f , will the rays converge to a point after they have passed through the lens?

Tutor. They will: thus if the candle be placed at g , (Plate II. Fig. 11.) the rays, after passing through the lens, will meet at x ; and this point will be more or less distant from the glass according as the candle is nearer to, or farther from the focus. • Where the rays meet, they form an inverted image of the flame of the candle.

James. Why so?

Tutor. Because that is the point where the rays, if they are not stopped, cross each other. To satisfy you on this head, I will hold up before you a point a sheet of paper, and you now see the flame of the candle is inverted.

James. How is this explained?

Tutor. Let $A B C$ (Plate II. Fig. 12.) represent an arrow placed beyond the focus of a double convex lens $d e f$, some rays will pass from every part of the arrow, and fall on the lens; but we shall consider only those which flow from the points A , B , and C . The rays which come from A , as $A d$, $A e$, and $A f$, will be refracted by the lens, and meet in a point

come from B , as Bd , Be , and Bf , will in b , and those which come from c , will in c .

Charles. I see clearly how the rays from B are refracted, and unite in b ; but it is not so with regard to those from the extremity A and c .

Tutor. I admit it: but you must remember the difficulty consists in this, the rays fall more obliquely on the glass from those points than in the middle, and therefore the refraction is very different. The ray Bf in the centre suffers no refraction, Bd is refracted into b ; and if another ray went from N , as Nd , it would be refracted to n , somewhere between b and a , and the rays from A must, for the same reason, be refracted to a .

James. If the subject ABC is brought nearer the glass, will the picture be removed to a greater distance?

Tutor. It will: for then the rays will fall more diverging upon the glass, and cannot be so soon collected into the corresponding points behind it.

Charles. From what you have said, I see that the object ABC be placed in F , the rays, after refraction, will go out parallel to one another: and if brought nearer to the glass than F , then they will diverge from one another, so that in neither case an image will be formed behind the lens.

OPTICS.

James. To get an image, must the object be beyond the focus F?

Tutor. It must: and the picture will be either more or less than the object, as its distance from the glass is greater or less than the distance of the object; if $A B C$ (Fig. 12) be the object, A will be the picture; and if $c b A$ be the object, $A B C$ will be the picture.

Charles. Is there any rule to find the distance of the picture from the glass?

Tutor. If you know the focal distance of the glass, and the distance of the object from the glass, the rule is this:

“Multiply the distance of the focus, by the distance of the object, and divide the product by their difference, the quotient is the distance of the picture.”

James. If the focal distance of the glass be seven inches, and the object be nine inches from the lens, I say,

$$7 \times 9 = 63$$

$$\frac{63}{2} = 31\frac{1}{2} \text{ inches, of course the picture}$$

will be very much larger than the object as you have said, the picture is as much more or less than the object, as its distance from the glass is greater or less than the distance of the object.

Tutor. If the focus be seven inches from the object at the distance of seventeen in

the distance of the picture will be found thus

$$7 \times 17 = 119$$

$$\frac{119}{10} = \frac{119}{10} = 12 \text{ inches nearly.}$$

CONVERSATION VII.

Images of Objects inverted—Of the Scioptric Ball—Of Lenses and their Foci.

James. Will the image of a candle, when received through a convex lens, be inverted?

Tutor. It will, as you shall see: Here is no light in this room but from the candle, the rays of which pass through a convex lens, and by holding a sheet of paper in a proper place, you will see a complete inverted image of the candle on it.

An object seen through a very small aperture appears also inverted, but it is very imperfect compared to an image formed with the lens; it is *faint* for want of light, and it is *confused* because the rays interfere with one another.

Charles. What is the reason of its being inverted?

Tutor. Because the rays from the extreme parts of the object must cross at the hole. If you look through a very small hole at any object, the object appears magnified. Make a pin-hole in a sheet of brown paper, and look through it at the small print of this book.

James. It is, indeed, very much magnified.

Tutor. As an object approaches a convex lens, its image departs from it: and as the object recedes, its image advances. Make the experiment with a candle and a lens, properly mounted in a long room: when you stand at one end of the room, and throw the image on the opposite wall, the image is large, but as you come nearer to the wall, the image is small, and the distance between the candle and glass is very much increased.

I will now show you an instrument, called a *Scioptric Ball*, which is fastened into a window-shutter of a room from which all light is excluded except what comes in through this glass.

Charles. Of what does this instrument consist?

Tutor. Of a frame *A B* (Plate II. Fig. 13.) and a ball of wood *c*, in which is a glass lens; and the ball moves easily in the frame in all directions, so that the view of any surrounding objects may be received through it.

James. Do you screw this frame into the shutter?

Tutor. Yes, a hole is cut in it for that purpose; and there are little brass screws belonging to it, such as those marked *s*. When it is fixed in its place a screen must be set at a proper distance from the lens to receive on it images of the objects out of doors. This instrument is sometimes called an artificial eye.

Charles. In what respect is it like the eye?

Tutor. The frame has been compared to the socket in which the eye moves, and the wooden ball to the whole globe of the eye; the hole in the ball represents the pupil, the convex lens corresponds to the crystalline humour,* and the screen to the retina.

James. The ball by turning in all directions is very like the eye, for without moving the head I can look on all sides, and upwards and downwards.

Tutor. Well, we will now place the screen properly, and turn the ball to the garden:—Here you see all the objects perfectly expressed.

James. But they are all inverted.

Tutor. That is the great defect belonging to this instrument; but I will tell you how it may be remedied: take a looking-glass and hold it before you with its face towards the picture on the screen, and inclining a little downwards,

* These terms will be explained hereafter.

and the images will appear erect in the and even brighter than they were on the s

Charles. You have shown us in what n the rays of light are refracted by conves, when those rays are parallel. Will not be a difference if the rays *converge*, *xerge*, before they enter the lens?

Tutor. Certainly: if rays *converge* they enter a convex lens, they will be col at a point *nearer* to the lens than the fo parallel rays. But if they *diverge* befor enter the lens, they will then be collecte point *beyond* the focus of parallel rays.

There are concave lenses as well as co and the refraction which takes place by of these differs from that which I have a explained.

Charles. What will the effect of refr be, when parallel rays fall upon a doubl cave lens?

Tutor. Suppose the parallel rays *a*, *b* &c. (Plate II. Fig. 14.) pass through th A B, they will *diverge* after they have] through the glass.

James. Is there any rule for ascertaini degree of divergency?

Tutor. Yes; it will be precisely so m if the rays had come from a radiant po which is the centre of the concavity of the

Charles. Is that point called the focus?

Tutor. It is called the *virtual* or *imag*

focus. Thus the ray *a*, after passing through the glass *AB*, will go on in the direction *gh*, as if it had come from the point *x*, and no glass been in the way: the ray *b*, would go on in the direction *mn*, and the ray *c* in the direction *rs*, and so on. The ray *c x* in the centre suffers no refraction, but proceeds precisely as if no glass had been in the way.

James. Suppose the lens had been concave only on one side, and the other side had been flat, how would the rays have diverged?

Tutor. They would have diverged after passing through it, as if they had come from a radiant point at the distance of a whole diameter of the convexity of the lens.

Charles. There is then a great similarity in the refraction of the convex and concave lens.

Tutor. True: the *focus* of a double convex is at the distance of the radius of convexity, and so is the *imaginary focus* of the double concave: and the *focus* of the plano-convex is at the distance of the diameter of the convexity, and so is the *imaginary focus* of the plano-concave.

You will find that images formed by a concave lens, or those formed by a convex lens, where the object is *within* its principal focus, are in the same position with the objects they represent: they are also *imaginary*, for the refracted rays never meet at the foci whence they seem to diverge.

F

But the images of objects placed beyond the focus of a convex lens are inverted, and *real*, for the refracted rays do meet at their proper foci.

CONVERSATION VIII.

Of the Nature and Advantages of Light—Of the Separation of the Rays of Light by means of a Prism—And of compounded Rays, &c.

Tutor. We cannot contemplate the nature of light without being struck with the great advantages which we enjoy from it. Without that blessing our condition would be truly deplorable.

Charles. I well remember how feelingly Milton describes his situation after he lost his sight :

With the year
Seasons return; but not to me returns
Day, or the sweet approach of ev'n or morn,
Or sight of vernal bloom, or summer's rose,
Or flocks, or herds, or human face divine;
But cloud instead, and ever-during dark
Surrounds me, from the cheerful ways of men

Cut off, and for the book of knowledge fair,
Presented with an universal blank
Of Nature's works, to me expung'd and raz'd,
And wisdom, at one entrance, quite shut out.

Tutor. Yet his situation was rendered comfortable by means of friends and relations, who all possessed the advantages of light. But if our world were deprived of light, what pleasure or even comfort could we enjoy? "How," says a good writer, "could we provide ourselves with food, and the other necessities of life? How could we transact the least business? How could we correspond with each other, or be of the least reciprocal service without light, and those admirable organs of the body, which the Omnipotent Creator has adapted to the perception of this inestimable benefit?"

James. But you have told us that the light would be of comparatively small advantage without an atmosphere.

Tutor. The atmosphere not only *refracts* the rays of the light, so that we enjoy longer days than we should without it, but occasions that twilight, which is so beneficial to our eyes; for without it the appearance and disappearance of the sun would have been instantaneous; and in every twenty-four hours we should have experienced a sudden transition from the brightest sun-shine to the most profound darkness, and from thick darkness to a blaze of light.

Charles. I know how painful that would be,
VOL. III.—E

from having slept in a very dark room, having suddenly opened the shutters when sun was shining extremely bright.

Tutor. The atmosphere reflects also the in every direction, and if there were no atmosphere, the sun would benefit those only looked towards it, and to those whose backs were turned to that luminary it would add darkness. Ought we not therefore gratefully to acknowledge the wisdom and goodness of the Creator, who has adapted these things to the advantage of his creatures; and may we not with Thomson devoutly exclaim:

How then shall I attempt to sing of Him
Who, light himself, in uncreated light
Invested deep, dwells awfully retired
From mortal eye, or angel's purer ken;
Whose single smile has, from the first of time,
Fill'd, overflowing, all yon lamps of heaven,
That beam for ever through the boundless sky:
But, should He hide his face, th' astonish'd sun,
And all the extinguish'd stars would loosening reel
Wide from their spheres, and Chaos come again.—

James. I saw in some of your experiments that the rays of light, after passing through glass, were tinged with different colours, is the reason of this?

Tutor. Formerly light was supposed to be a simple and uncompounded body; Sir Isaac Newton, however, discovered that it was not a simple substance, but was composed of sev-

parts, each, of which has a different degree of refrangibility.

Charles. How is that shown?

Tutor. Let the room be darkened, and let there only be a very small hole in the shutter to admit the sun's rays; instead of a lens I take a triangular piece of glass, called a *prism*; now as in this there is nothing to bring the rays to a focus, they will, in passing through it, suffer different degrees of refraction, and be separated into the different coloured rays, which being received on a sheet of white paper, will exhibit the seven following colours: *red, orange, yellow, green, blue, indigo, and violet*; and now you shall hear a poet's description of them.

First the flaming *red*
 Sprung vivid forth; the tawny *orange* next:
 And next delicious *yellow*; by whose side
 Fell the kind beams of all-refreshing *green*.
 Then the pure *blue*, that swells autumnal skies,
 Ethereal play'd; and then, of sadder hue,
 Emerg'd the deepen'd *indigo*, as when
 The heavy skirted evening droops with frost,
 While the last gleamings of refracted light
 Dy'd in the fainting *violet* away.

THOMSON.

James. Here are all the colours of the rainbow: the image on the paper is a sort of oblong.

Tutor. That oblong image is usually called a *spectrum*, and if it be divided into 360 equal

parts, the red will occupy forty-five, the orange twenty-seven, the yellow forty, the green and the blue sixty each, the violet eighty.

Charles. The shade of difference in these colours seems very small indeed.

Tutor. You are not the only person who has made this observation; some experimental philosophers say there are but three or truly distinct colours, viz. the *red*, *yellow*, and *blue*.

Charles. What is called the *orange* is only a mixture of red and yellow, between which it is situated.

Tutor. In like manner the green is a mixture of the yellow and blue, and the violet is but a fainter tinge of the indigo.

James. How is it then that light, which consists of different colours, is usually white?

Tutor. By mixing the several colours in proper proportion white may be produced.

James. Do you mean to say that a mixture of red, orange, yellow, green, blue, indigo, and violet, in any proportion, will produce white?

Tutor. If you divide a circular surface into 360 parts, and then paint it in the proportions just mentioned, that is, forty-five of red, twenty-seven orange, forty-eight yellow, sixty green, sixty blue, eighty indigo, &c. and turn it round with great velocity, the whole will appear of a dirty white,

colours were more perfect the white would be so too.

James. Was it then owing to the separation of the different rays, that I saw the rainbow colours about the edges of the image made with the lens?

Tutor. It was: some of the rays were scattered, and not brought to a focus, and these were divided in the course of refraction. And I may tell you now, though I shall not explain it at present, that the rainbow in the heavens is caused by the separation of the rays of light into their component parts.

Charles. And was that the cause of the colours which we saw on some soap bubbles which James was making with a tobacco-pipe?

Tutor. It was.

CONVERSATION IX.

Of Colours.

Charles. After what you said yesterday, I am at a loss to know the cause of different colours; the cloth on this table is green; that of which

my coat is made is blue, what makes the difference in these? Am I to believe the poet, that

Colours are but phantoms of the day,
With that they're born, with that they fade away ;
Like beauty's charms, they but amuse the sight,
Dark in themselves, till by reflection bright ;
With the sun's aid, to rival him they boast,
But light withdraw, in their own shades are lost.

HUMPH.

Tutor. All colours are supposed to exist only in the light of luminous bodies, such as the sun, a candle, &c. and that light falling incessantly upon different bodies is separated into its seven primitive colours, some of which are absorbed, while others were reflected.

James. Is it from the reflected rays that we judge of the colour of objects?

Tutor. It has generally been thought so; thus the cloth on the table absorbs all the rays but the green, which it reflects to the eye; but your coat is of a different texture, and absorbs all but the blue rays.

Charles. Why is paper and the snow white?

Tutor. The whiteness of paper is occasioned by its reflecting the greatest part of all the rays that fall upon it. And every flake of snow being an assemblage of frozen globules of water sticking together, reflects and refracts the light that falls upon it in all directions so as to mix it very intimately, and produce a white image on the eye.

James. Does the whiteness of the sun's light arise from a mixture of all the primary colours?

Tutor. It does, as may be easily proved by an experiment, for if any of the seven colours be intercepted at the lens, the image in a great measure loses its whiteness. With the prism I will divide the ray into its seven colours,* I will then take a convex lens in order to re-unite them into a single ray, which will exhibit a round image of a shining white; but if only five or six of these rays be taken with the lens, it will produce a dusky white.

Charles. And yet to this white colour of the sun we are indebted for all the fine colours exhibited in nature:

Fairest of beings! first created light!
Prime cause of beauty! for from thee alone,
The sparkling gem, the vegetable race,
The nobler worlds that live and breathe, their charms,
The lovely hues peculiar to each tribe,
From thy unfailing source of splendour draw.

MALLET.

Tutor. These are very appropriate lines, for without light the diamond would lose all its beauty.

James. The diamond, I know, owes its brilliancy to the power of reflecting almost all the

* A figure will be given on this subject with explanations, Conversation XVIII. on the Rainbow.

rays of light that fall on it: but are v
and animal tribes equally indebted to it

Tutor. What does the gardener do
his endive and lettuces white?

Charles. He ties them up.

Tutor. That is, he shuts out the li
by this means they become blanched.
produce you a thousand instances to sh
only that the colour, but even the exis
vegetables, depend upon light. Close
trees have only leaves on the outside,
the cedar in the garden. Look up th
of a yew tree, and you will see that t
branches are almost, or altogether b
leaves. Geraniums and other green-hou
turn their flowers to the light; and p
general, if doomed to darkness, soon sic
die.

James. There are some flowers, the
which are, in different parts, of diffe
lours, how do you account for this?

Tutor. The flower of the hearts-case i
kind, and if examined with a good mic
it will be found that the *texture* of the l
yellow parts is very different. The te
the leaves of the white and red rose is
ferent. Clouds also which are so va
their colours are undoubtedly more
dense, as well as being differently plac
regard to the eye of the spectator;

whole depend on the light of the sun for their beauty, to which the poet refers :—

But see, the flush'd horizon flames intense
 With vivid red, in rich profusion stream'd
 O'er heaven's pure arch. At once the clouds assume
 Their gayest liveries; *these* with silvery beams
 Fring'd lovely; splendid *those* in liquid gold :
 And speak their sovereign's state. He comes, behold !
 Fountain of light and colour, warmth and life !
 The king of glory !

MALLET.

Charles. Are we to understand that all colours depend on the reflection of the several coloured rays of light ?

Tutor. This seems to have been the opinion of Sir Isaac Newton ; but he concluded from various experiments on this subject, that every substance in nature, provided it be reduced to a proper degree of thinness, is transparent. Many transparent media reflect one colour, and transmit another : gold-leaf reflects the yellow but it transmits a sort of green colour by holding it up against a strong light.

Mr. Delaval, a gentleman who a few years since made many experiments to ascertain how colours are produced, undertakes to show that they are exhibited by transmitted light alone and not by reflected light.

James. I do not see how that can be the case with bodies that are not transparent.

Tutor. He infers from his experiments, w
you may hereafter examine for yourselves,
the original fibres of all substances, when cl
ed of heterogeneous matter, are perfectly w
and that the rays of light are reflected
these white particles through the colouring
ter with which they are covered, and that
colouring matter serves to intercept certain
in their passage through it, while a free pas
being left to others, they will exhibit, accor
to these circumstances, different colours.—
red colour of the shells of lobsters after boil
he says, is only a superficial covering sp
over the white calcareous earth, of which
shells are composed, and may be removed
scraping or filing. Before the applicatio
heat, it is so thick as to appear black, being
thick to admit the passage of light to the s
and back again. The case is the same
feathers, which owe their colours to a thin la
of transparent matter on a white ground.

CONVERSATION X.

Reflected Light, and Plain Mirrors.

Tutor. We now come to treat of a different species of glasses, viz. *mirrors*, or, as they are sometimes called, *specula*.

James. A looking-glass is a mirror, is it not?

Tutor. Mirrors are made of glass, silvered on one side; they are also made of highly polished metal. There are three kinds of mirrors, the *plain*, the *convex*, and the *concave*.

Charles. You have shown us that in a looking-glass or plain mirror, “The angle of reflection is always equal to the angle of incidence.”*

Tutor. This rule is not only applicable to plain mirrors, but to those which are convex and concave also, as I shall show you to-morrow. But I wish to make some observations first on plain mirrors. In the first place, if you wish to see the complete image of yourself in a plain mirror or looking-glass, it must be *half* as long as you are high.

James. I should have imagined the glass must have been as long as I am high.

* See p. 18.

Tutor. In looking at your image does it not seem to be as far behind you stand before it.

James. Yes : and if I move forwards, the image behind the glass approach or recede.

Tutor. Let $a b$ (Plate II. Fig. looking-glass, and A the spectator, posite to it. The ray from his eye reflected in the same line $A a$, but flowing from his foot, in order to be eye, must be reflected by the line b

Charles. So it will, for if $x b$ perpendicular to the glass, the incidence be $c b x$, equal to the reflected angle

Tutor. And therefore the foot will behind the glass at D along the line A , that is the line in which the ray last the eye.

James. Is that part of the glass intercepted by the lines $A B$ and $A D$, equal half the length of $B D$, or $A c$?

Tutor. It is ; $A a b$ and $A B D$ supposed to form two triangles, the sides always bear a fixed proportion to one another, and if $A B$ is double of $A a$, as, in the figure, $B D$ will be double of $a b$, or at least of the glass intercepted by $A B$ and

Charles. This will hold true, in whatever distance we please from the glass

Tutor. If you walk towards a lo

your image will approach, but with a double velocity, because the two motions are equal and contrary. But if, while you stand before a looking-glass, your brother walk up to you from behind, his image will appear to you to move at the same rate as he walks, but to him the velocity of the image will appear to be double; for with regard to you, there will be but one motion, but with regard to him, there will be two equal and contrary ones.

James. If I look at the reflection of a candle in a looking-glass, I see in fact two images, one much fainter than the other, what is the reason of this?

Tutor. The same may be observed of any object that is strongly illuminated, and the reason of the double image is, that a part of the rays are immediately reflected from the upper surface of the glass which form the faint image, while the greater part of them are reflected from the farther surface, or silvering part, and form the vivid image. To see these two images you must stand a little sideways, and not directly before the glass.

Charles. What is meant by the expression of "An image being formed behind a reflector?"

Tutor. It is intended to denote that the reflected rays come to the eye with the same inclination as if the object itself were actually behind the reflector. If you, standing on one side of the room, see the image of your brother,

who is on the other side, in the looking-glass, the image seems to be formed behind the glass, that is, the rays come to your eye precisely in the same way as they would if your brother himself stood in that place, without the intervention of a glass.

James. But the image in the glass is not so bright or vivid as the object.

Tutor. A plain mirror is in theory supposed to reflect all the light which falls upon it, but in practice nearly half the light is lost on account of the inaccuracy of the polish, &c.

Charles. Has it not been said, that Archimedes, at the siege of Syracuse, burned the ships of Marcellus, by a machine composed of mirrors?

Tutor. Yes: but we have no certain account that may be implicitly relied on. Mr. Buffon, about fifty or sixty years ago, burned a plant at the distance of seventy feet, with forty plain mirrors.

James. I do not see how they can act as burning glasses.

Tutor. A plain mirror reflects the light and heat coming from the sun, and will illuminate and heat any substance on which they are thrown, in the same manner as if the sun shone upon it. Two mirrors will reflect on it a double quantity of heat; and if 40 or 100 mirrors could be so placed as to reflect from each the heat

coming from the sun, or any particular substance, they would increase the heat 40 or 100 times.

CONVERSATION XI.

Of Concave Mirrors—their Uses—how they act.

James. To what uses are concave mirrors applied?

Tutor. They are chiefly used in reflecting telescopes; that is, in telescopes adapted to viewing the heavenly bodies. And as you like to look at Jupiter's little moons, and Saturn's ring, through my telescope, it may be worth your while to take some pains to know by what means this pleasure is afforded you.

Charles. I shall not object to any attention necessary to comprehend the principles on which these instruments are formed.

Tutor. A B (Plate II. Fig. 16.) represents a concave mirror, and *a, b, c, d, e, f*, three parallel rays of light falling upon it. *c* is the centre of concavity, that is, one leg of your compasses being placed on *c*, and then open them to the

length $c d$, and the other leg will touch the mirror $A B$ in all its parts.

James. Then all the lines drawn from c to the glass will be equal to one another, as $c b$, $c d$, and $c f$?

Tutor. They will: and there is another property belonging to them; they are all perpendicular to the glass, in the parts where they touch.

Charles. That is $c b$ and $c f$ are perpendicular to the glass at b and f , as well as $c d$ at d .

Tutor. Yes, they are:— $c d$ is an *incident ray*, but as it passes through the centre of concavity, it will be reflected back in the same line, that is, as it makes no angle of incidence, so there will be no angle of reflection: $a b$ is an *incident ray*, and I want to know what will be the direction of the reflected ray?

Charles. Since $c b$ is perpendicular to the glass at b , the angle of incidence is $a b c$; and as the angle of reflection is always equal to the angle of incidence, I must make another angle, as $c b m$, equal to $a b c$,* and then the line $b m$ is that in which the incident ray will move after reflection.

* To make an angle $c b m$, equal to another given one, as $a b c$. From b as a centre with any radius $b x$, describe the arc $x o$, which will cut $c b$ in z , take the distance $x z$ in your compasses, and set off with it $z o$, and then draw the line $b o m$, and the angle $m b c$ is equal to the angle $a b c$.

Tutor. Can you, James, tell me how to find the line in which the incident ray ef will move after reflection?

James. Yes: I will make the angle cfm equal to $cf e$, and the line fm will be that in which the reflected ray will move; therefore ef is reflected to the same point m as ab was.

Tutor. If, instead of two incident rays, any number were drawn parallel to cd , they would every one be reflected to the same point m ; and that point which is called *the focus of parallel rays* is distant from the mirror equal to half the radius cd .

James. Then we may easily find the point, without the trouble of drawing the angles, merely by dividing the radius of concavity into two equal parts.

Tutor. You may.—The rays, as we have already observed, which proceed from any point of a celestial object, may be esteemed parallel at the earth, and therefore the image of that point will be formed at m .

Charles. Do you mean that all the rays flowing from a point of a star, and falling upon such a mirror, will be reflected to the point m , where the image of the star will appear?

Tutor. I do, if there be any thing at the point m , to receive the image.

James. Will not the same rule hold with regard to terrestrial objects?

Tutor. No: for the rays which proceed from

any terrestrial object, however remote, cannot be esteemed strictly parallel, they therefore come *diverging*; and will not be converged to a *single point*, at the distance of half the radius of the mirror's concavity from the reflecting surface; but in *separate points*, at a little greater distance from the mirror than half the radius.

Charles. Can you explain this by a figure?

Tutor. I will endeavour to do so. Let $A B$ (Plate II. Fig. 17.) be a concave mirror, and M E any remote object, from every part of which rays will proceed to every point of the mirror; that is, from the point M rays will flow to every point of the mirror, and so they will from E , and from every point between these extremities. Let us see where the rays that proceed from M to A , C , and B will be reflected, or, in other words, where the image of the point M will be formed.

James. Will all the rays that proceed from M , to different parts of the glass, be reflected to a single point?

Tutor. Yes, they will, and the difficulty is to find that point: I will take only three rays, to prevent confusion, viz. $M A$, $M C$, $M B$; and C is the centre of concavity of the glass.

Charles. Then if I draw $C A$, that line will be perpendicular to the glass at the point A : the angle $M A C$ is now given, and it is the angle of incidence.

James. And you must make another equal to it, as you did before.

Tutor. Very well; make $c \Delta x$ equal to $m \Delta c$, and extend the line Δx to any length you please.

Now you have an angle $m c c$ made with the ray $m c$, and the perpendicular $c c$, which is another angle of incidence.

Charles. I will make the angle of reflection $c c x$ equal to it, and the line $c x$ being produced, cuts the line Δx in a particular point, which I will call m .

Tutor. Draw now the perpendicular $c u$, and you have with it, and the ray $m u$, the angle of incidence $m u c$: make another angle equal to it, as its angle of reflection.

James. There it is $c u u$, and I find the line $u u$ meets the other lines at the point m .

Tutor. Then m is the point in which all the reflected rays of M will converge; of course the image of the extremity M of the arrow $E M$ will be formed at m . Now the same might be shown of every other part of the object $M E$, the image of which will be represented by $e m$, which you see is at a greater distance from the glass than half $c c$, or radius.

Charles. The image is *inverted* also, and *less* than the object.

CONVERSATION XII.

Of Concave Mirrors, and Experiments on them.

Tutor. If you understand what we conversed on yesterday, and what you have yourselves done, you will easily see how the image is formed by the large concave mirror of the reflecting telescope, when we come to examine the construction of that instrument. In a concave mirror, the image is *less* than the object, when the object is more remote from the mirror than *c*, the centre of concavity, and in that case the image is between the object and mirror.

James. Suppose the object be placed in the centre *c*.

Tutor. Then the image and object will coincide: and if the object is placed nearer to the glass than the centre *c*, then the image will be more remote, and bigger than the object.

Charles. I should like to see this illustrated by an experiment.

Tutor. Well here is a large concave mirror: place yourself before it, beyond the centre of the concavity; and with a little care in adjusting your position, you will see an inverted image of yourself in the air between you and the mirror, and of a less size than you are.

OF CONCAVE MIRRORS.

When you see the image, extend your hand gently towards the glass, and the hand and image will advance to meet it, till they meet in the centre of the glass's concavity; if you carry your hand still farther, the hand and the image will pass by it, and come between the hand and the body: now move your hand to the other side, and the image of it will move towards the other.

James. Is there any rule for finding the distance at which the image of an object is formed from the mirror?

Tutor. If you know the radius of the mirror's concavity, and also the distance of the object from the glass,—

“Multiply the distance and radius together, and divide the product by double the distance less by the radius, and the quotient is the distance required.”

Tell me at what distance the image of an object will be, suppose the radius of the concavity of the mirror be 12 inches, and the object 18 inches from it.

James. I multiply 18 by 12, which is equal to 216; this I divide by double 12, or 24, which is 9; but 216 divided by 24 gives 9, which is the number of inches required.

Tutor. You may vary this example, in order to impress the rule on your memory; and I will show you another experiment. I take this glass partly full of water, and corked, and

it opposite the concave mirror, and beyond the focus, that it may appear to be reversed: now stand a little farther distant than the bottle, and you will see the bottle inverted in the air, and the water which is in the lower part of the bottle will appear to be in the upper.—I will invert the bottle, and uncork it, and whilst the water is running out, the image will appear to be filling but when the bottle is empty, the illusion is at an end.

Charles. Are concave mirrors ever used as burning-glasses?

Tutor. Since it is the property of these mirrors to cause parallel rays to converge to a focus, and since the rays of the sun are considered as parallel, they are very useful as burning glasses, and the principal focus is the burning point.

James. Is the image formed by a concave mirror always before it?

Tutor. In all cases, except when the object is nearer to the mirror than the principal focus.

Charles. Is the image then behind the mirror?

Tutor. It is; and farther behind the mirror than the object is before it. Let AC (Plate III Fig. 18.) be a mirror, and xz the object between the centre K of the glass, and the glass itself; and the image xy will be behind the glass erect, curved, and magnified, and o

course the image is farther behind the glass than the object is before it.

James. What would be the effect, if, instead of an opaque object xz , a luminous one, as a candle, were placed in the focus of a concave mirror?

Tutor. It would strongly illuminate a space of the same dimension as the mirror to a great distance: and if the candle were still nearer the mirror than the focus, its rays will enlighten a larger space. Hence you may understand the construction of many of the lamps which are now to be seen in many parts of London, and which are undoubtedly a great improvement in lighting the streets.

CONVERSATION XIII.

Of Concave and Convex Mirrors.

Tutor. We shall devote another morning or two to the subject of reflection from mirrors of different kinds.

Charles. You have not said any thing about *convex* mirrors, and yet they are now very

much in fashion in handsome drawing-rooms: I have seen several, and always observed that the image was very much less than the object.

Tutor. A convex mirror is an ornamental piece of furniture, especially if it can be placed before a window, either with a good prospect; or where there are a number of persons passing and repassing in their different employments. The images reflected from these are smaller than the objects, erect, and behind the surface, therefore a landscape or a busy scene delineated on one of them, is always a beautiful object to the eye. For the same reason, a glass of this kind, in a room in which large assemblies meet, forms an extremely interesting picture. You may easily conceive how the convex mirror diminishes objects, or the images of objects, by considering in what manner they are magnified by the concave mirror. If $x y z$ (Fig. 18.) were a straight object before a *convex* mirror Δc , the image by reflection would be $x z$.

James. Would it not appear curved?

Tutor. Certainly: for if the object be a right line, or a plain surface, its image must be curved, because the different points of the object are not equally distant from the reflector. In fact, the images formed by convex mirrors, if accurately compared with the objects, are never exactly of the same shape.

Charles. I do not quite comprehend in what

manner reflection takes place at a convex mirror.

Tutor. I will endeavour, by a figure, to make it plain: *c d* (Plate III. Fig. 19.) represents a convex mirror standing at the end of a room, before which the arrow *A B* is placed on one side, or obliquely: where must the spectator stand, to see the reflected image?

Charles. On the other side of the room.

Tutor. The eye *E* will represent that situation:—the rays from the external parts of the arrow, *A* and *B*, flow convergingly along *A a* and *B b*, and if no glass were in the way, they would meet at *P*; but the glass reflects the ray *A a* along *a E*, and the ray *B b* along *b E*; and as we always transfer the image of an object in that direction in which the rays approach the eye, we see the image of *A* along the line *E a* behind the glass, and the image of *B* along *E b*, and, of course, the image of the whole arrow is at *s*.

By means of a similar diagram, I will show you more clearly the principle of the *concave* mirror. Suppose an object *e* (Plate III. Fig. 20.) to be beyond the focus *F*, and the spectator to stand at *z*, the rays *e b* and *e d* are reflected, and where they meet in *E* the spectator will see the image.

James. That is between himself and the object.

Tutor. He must, however, be far enough

CONVERSATION XIV.

Of Convex Reflection—Of Optical Delusions—Of Anamorphoses.

Charles. You cannot, I see, make the same experiment with the candle, and a convex mirror, that you made yesterday with the concave one.

Tutor. Certainly, because the image is formed behind the glass: but it may, perhaps, be worth our while to consider how the effect is produced in a mirror of this kind. Let *a* (Plate III. Fig. 22.) represent a convex mirror and *Af* be half the radius of convexity, and take *AF*, *FO*, *OB*, &c. each equal *Af*. If incident rays flow from 2, the reflected rays will appear to come from behind the glass at $\frac{1}{2}$.

James. Do you mean if a candle be placed at 2, the image of it will appear to be formed at behind the glass?

Tutor. I do: and if that, or any other object be carried to 3, 4, &c. the image will also go backward to $\frac{1}{3}$, $\frac{1}{4}$, &c.

Charles. Then, as a person walks towards a convex spherical reflector, the image appears to walk towards him, constantly increasing in

magnitude, till they touch each other at the surface.

Tutor. You will observe that the image, however distant the object, is never farther off than at f ; that is, the imaginary focus of parallel rays.

James. The difference then between convex and concave reflectors is, that the point f in the former is behind the glass, and in the latter it is before the glass at F .

Tutor. Just so : from the property of diminishing objects, spherical reflectors are not only pleasing ornaments for our best rooms, but are much used by all lovers of picturesque scenery. "Small convex reflectors," says Dr. Gregory, "are made for the use of travellers, who, when fatigued by stretching the eye to Alps towering on Alps, can, by their mirror, bring these sublime objects into a narrow compass, and gratify the sight by pictures which the art of man in vain attempts to imitate."*

Concave mirrors have been used for many other and different purposes ; for by them, with a little ingenuity, a thousand illusions may be practised on the ignorant and credulous.

Charles. I remember going with you to see an exhibition in Bond street, which you said depended on a concave mirror ; I was desired to look into a glass, I did so, and started back,

* See Economy of Nature, Vol. L p. 26, 2d Edition.

for I thought the point of a dagger would have been in my face. I looked again, and a death's head snapped at me; and then I saw a most beautiful nosegay, which I wished to grasp, but it vanished in an instant.

Tutor. I will explain how these deceptions are managed: let $E F$ (Plate III. Fig. 23.) be a concave mirror, 10 or 12 inches in diameter, placed in one room; $A B$ the wainscot that separates the spectator from it; but in this there is a square or circular opening which faces the mirror exactly. A nosegay, for instance, is inverted at c , which must be strongly illuminated by means of an Argand's lamp; but no direct light from the lamp is to fall on the mirror. Now a person standing at G will see an image of the nosegay at D .

James. What is to make it vanish?

Tutor. In exhibitions of this kind there is always a person behind the wainscot, in league with the man that attends the spectator, who removes the real nosegay upon some hint understood between them.

Charles. Was it then upon the man behind the scene that the approaching sword and the advancing death's head, &c. depended?

Tutor. It was: and persons have undertaken to exhibit the ghosts of the dead by contrivances of this kind: for if a drawing of the deceased be placed instead of the nosegay, it may be done. But such exhibitions are not to be re-

commended, and indeed ought never to be practised, without explaining the whole process to the astonished spectator afterwards.

If a large concave mirror be placed before a blazing fire so as to reflect the image of the fire on the flap of a bright mahogany table, a spectator suddenly introduced in the room will suppose the fire to be on the table.

If two large concave mirrors A and B (Plate III. Fig. 24.) be placed opposite each other, at the distance of several feet, and red hot charcoal be put in the focus D, and some gunpowder in the other focus C, it will presently take fire. The use of a pair of bellows may be necessary to make the charcoal burn strongly.—

This experiment may be varied by placing a thermometer in one focus, and lighted charcoal in the other, and it will be seen that the quicksilver in the thermometer will rise as the fire increases, though another thermometer at the same distance from the fire, but not in the focus of the glass, will not be affected by it.

James. I have seen concave glasses in which my face has been rendered as long as my arm, or as broad as my body; how are these made?

Tutor. These images are called *anamorphoses*, and are produced from *cylindrical* concave mirrors; and as the mirror is placed either *upright*, or on its *side*, the image of the picture is distorted into a very long or a very broad image.

Reflecting surfaces may be made of various

shapes, and if a regular figure be placed on an irregular reflector, the image will be formed, but if an object, as a picture, be deformed, according to certain rules, it will appear regular. Such figures and instruments are sold by opticians, and they serve to instruct those who are ignorant of these subjects.

CONVERSATION XV.

Of the different Parts of the Eye.

Charles. Will you now describe the parts and construction of the telescope?

Tutor. I think it will be better first to explain the several parts of the eye, and the nature of vision in the simple state, before we treat of those instruments which are used to assist it.

James. I once saw a bullock's eye dissected and was told that it imitated a human eye in several parts.

Tutor. The eye, when taken from the socket, is of a globular form, and it is composed

coats or skins, and three other substances called humours. This figure (Plate III. Fig. 25.) represents the section of an eye, that is, an eye cut down the middle; and Fig. 26, the front view of an eye as it appears in the head.

Charles. Have these coats and humours all different names?

Tutor. Yes: the external coat, which is represented by the outer circle *A B C D E*, is called the *sclerotica*; the front part of this, namely, *c x D*, is perfectly transparent, and is called the *cornea*; beyond this, towards *B* and *E*, it is white, and called the white of the eye. The next coat, which is represented by the second circle, is called the *choroides*.

James. This circle does not go all round.

Tutor. No: the vacant space *a b* is that which we call the pupil, and through this alone the light is allowed to enter the eye.

Charles. What do you call that part, which is of a beautiful blue in some persons, as in cousin Lydia; and in others brown, or almost black?

Tutor. That, as *a c*, *b e*, is part of the *choroides*, and is called the *iris*.

Charles. The iris is sometimes much larger than it is at another.

Tutor. It is composed of a sort of net-work, which contracts or expands according to the force of the light in which it is placed. Let

James stand in a dark corner for two or three minutes:—now look at his eyes.

Charles. The *iris* of each is very small, and the pupil large.

Tutor. Now let him look steadily, rather close to the candle.

Charles. The iris is considerably enlarged, and the pupil of the eye is but a small point in comparison of what it was before.

Tutor. Did you never feel uneasy after sitting some time in the dark, when candles were suddenly brought into the room?

James. Yes: I remember last Friday evening we had been sitting half an hour almost in the dark at Mr. W——'s, and when candles were introduced, every one of the company complained of the pain which the sudden light occasioned.

Tutor. By sitting so long in the dark, the iris was contracted very much, of course the pupil being large, more light was admitted than it could well bear, and therefore till time was allowed for the iris to adjust itself, the uneasiness would be felt.

Charles. What do you call the third coat, which, from the figure, appears to be still less than the choroides?

Tutor. It is called the *retina*, or net-work, which serves to receive the images of objects produced by the refraction of the different hu-

mours of the eye, and painted, as it were, on the surface.

Charles. Are the humours of the eye intended for refracting the rays of light, in the same manner as glass lenses?

Tutor. They are; and they are called the *vitreous*, the *crystalline*, and the *aqueous* humours. The *vitreous* humour fills up all the space $z z$, at the back of the eye; it is nearly of the substance of melted glass. The *crystalline* is represented by $d f$, in the shape of a double convex lens: and the *aqueous*, or watery humour, fills up all that part of the eye between the crystalline humour, and the cornea $c x d$.

James. What does the part A at the back of the eye represent?

Tutor. It is the optic nerve, which serves to convey to the brain the sensations produced on the retina.

Charles. Does the retina extend to the brain?

Tutor. It does: and we shall, when we meet next, endeavour to explain the office of these humours in effecting vision. In the meantime, I would request you to consider again what I have told you of the different parts of the eye; and examine, at the same time, both figures; viz. 25 and 26.

James. We will: but you have said nothing about the uses of the eye-brows and eye-lashes.

Tutor. I intended to have reserved this to another opportunity: but I may now say, that the

eye-brows defend the eye from too strong light; and they prevent the eyes from injury by the sliding of substances down the forehead into them.

The eye-lids act like curtains to cover and protect the eyes during sleep: when we are awake, they diffuse a fluid over the eye, which keeps it clean, and well adapted for transmitting the rays of light.

The eye-lashes, in a thousand instances, guard the eye from danger, and protect it from entering dust, with which the atmosphere about

CONVERSATION XVI.

Of the Eye, and the Manner of Vision.

Charles. I do not understand what you mean when you said the optic nerve served to convey to the brain the sensations produced on the retina.

Tutor. Nor do I pretend to tell you in what manner the image of any object painted on the retina of the eye is calculated to convey to the mind an idea of that object: but I wish to

at the images of the various objects which are painted on the retina. Here is a man's eye, from the back part of which I cut the three coats, but so as to leave the vitreous humour perfect: I will now put against the vitreous humour a piece of white paper, and direct the eye towards the window; what do you see?

Ques. The figure of the window is drawn on the paper; but it is inverted.

Ans. Open the window, and you will see the trees in the garden drawn upon it in the inverted state, or any other bright object presented to it.

Ques. Does the paper, in this instance, represent the innermost coat called the retina?

Ans. It does; and I have made use of paper because it is easily seen through, whereas the retina is opaque; transparency would be of disadvantage to it. The retina, by means of the optic nerve, is conveyed to the brain, or, in other words, the optic nerve is an extension of the retina.

Ques. And does it carry the news of every thing that is painted on the retina?

Ans. So it should seem; for we have an instance of whatever is drawn upon it. I direct my eye towards you, and the image of your person is drawn on the retina of my eye, and I say I see you, and so of any thing else.

Ques. You said the rays of light proceed from the object.
VOL. III.—H

ing from external objects were refracted passing through the different humours of the

Tutor. They are, and converged to a point or there would be no distinct picture drawn on the retina, and of course no distinct idea conveyed to the mind. I will show you what I mean by a figure, taking an arrow again as an illustration.

As every point of an object $A B C$ (Plat. Fig. 27.) sends out rays in all directions, the rays from each point on the side next the eye will fall upon the cornea between $x y$, and after passing through the humours of the eye will be converged and brought to as many points on the retina, and will form on it a distinct inverted picture $c b a$ of the object.

James. This is done in the same manner as you showed us by means of a double convex lens.

Tutor. All three of the humours have the same effect in refracting the rays of light, but the crystalline is the most powerful, and that is why it is called a complete double convex lens: and you see the rays from A are brought to a point at a ; the rays from B will be converged at b , and those from C at c , and, of course, the intermediate ones between A and B , B and C will be formed between a and b , and b and c . Hence the object becomes visible by means of the image of it being drawn on the retina.

Charles. Since the image is inverted on

retina, how is it that we see things in the proper position ?

Tutor. This is a proper question, but one that is not very readily answered. It is well known that the sense of touch or feeling very much assists the sense of sight ; some paintings are so exquisitely finished, and so much resemble sculpture, that the eye is completely deceived, we then naturally extend the hand to aid the sense of seeing. Children who have to learn the use of all their senses, make use of their hands in every thing ; they see nothing which they do not wish to handle, and therefore it is not improbable, that by the sense of the touch, they learn, unawares, to rectify that of seeing. The image of a chair, or table, or other object, painted in an inverted position on the retina ; they feel and handle it, and find it erect ; the same result perpetually recurs, so that, at length, long before they can reason on the subject, or even describe their feelings by speech, the inverted image gives them an idea of an erect object.

Charles. I can easily conceive that this would be the case with common objects, such as are seen every day and hour. But will there be no difficulty in supposing that the same must happen with regard to any thing which I had never seen before ? I never saw ships sailing on the sea till within this month ; but when I first saw

them, they did not appear to me in an inverted position.

Tutor. But you have seen water and land fore, and they appear to you, by habit and experience, to be lowermost, though they are painted on the eye in a different position: the bottom of the ship is next the water, consequently, as you refer the water to the bottom, so you must the hull of the ship, which is connected with it. In the same manner, all parts of a distant prospect are right with respect to each other; and therefore, though there may be a hundred objects in the landscape entirely new to you, yet as they all bear a relation to one another, and to the earth on which they are, you refer them, by experience, to their erect position.

James. How is it that in so small a space on the retina of the eye, the images of so many objects can be formed?

Tutor. Dr. Paley* tells us, "The prospect from Hampstead Hill is compressed into the compass of a sixpence, yet circumstantially presented. A stage coach, travelling at an ordinary rate, for half an hour, passes in the eye only over the twelfth part of an inch,

* See Paley's *Natural Theology*, p. 35, seventh edition, or p. 13. in the *Analysis* of that work by the *Author of Dialogues*.

the change of place is distinctly perceived throughout its whole progress." Now what he asserts we all know is true: go to the window, and look steadily at the prospect before you, and see how many objects you can discern without moving your eye.

James. I can see a great number very distinctly indeed, besides which I can discern others, on both sides, which are not clearly defined.

Charles. I have another difficulty; we have two eyes, on both of which the images of objects are painted; how is it that we do not see every object double?

Tutor. When an object is seen distinctly with both eyes, the *axes* of them are directed to it, and the object appears single; for the optic nerves are so framed, that the correspondent parts, in both eyes, lead to the same place in the brain, and excite but one sensation. But if the axes of both eyes are not directed to the object, that object seems double.

James. How does that appear?

Tutor. Look at your brother, while I push your right eye out of its place towards the left.

James. I see two brothers, the one receding to the left hand of the other.

Tutor. The reason is this; by pushing the eye out of its natural place, the pictures in the two eyes do not fall upon correspondent parts

OPTICS.

retina, and therefore the sensations of the eye are excited in different parts, &c.

CONVERSATION XVII.

Of Spectacles, and of their Uses.

Charles. Why do people wear spectacles?

Tutor. To assist the sight, which may be defective from various causes. Some eyes are too flat, others are too convex: in some the humours lose a part of their transparency, & for that account, a deal of light that enters is stopt and lost in the passage, and every object appears dim. The eye, without spectacles, would be a useless machine. Spectacles are intended to collect the light, or to bring it to a proper degree of convergency.

Charles. Are spectacle-glasses always convex?

Tutor. No; they are convex when the eyes are too flat; but if the eyes are already too convex, then concave glasses are used. I know the properties of a convex glass,

James. Yes ; it is to make the rays of light converge sooner than they would without.

Tutor. Suppose then a person is unable to see objects distinctly, owing to the cornea $c d$ (Plate iv. Fig 28.) or to the crystalline $a b$, or both, being too flat. The focus of rays proceeding from any object, x , will not be on the retina, where it ought to be, but at ∞ beyond it.

Charles. How can it be beyond the eye ?

Tutor. It would be beyond it, if there were any thing to receive it ; as it is, the rays flowing from x , will not unite at d , so as to render vision distinct. To remedy this, a convex glass $m n$ is placed between the object and the eye, by means of which the rays are brought to a focus sooner, and the image is formed at d .

James. Now I see the reason why people are obliged, sometimes, to make trial of many pairs of spectacles, before they get those that will suit them. They cannot tell exactly what degree of convexity is necessary to bring the focus just to the retina.

Tutor. That is right ; for the shape of the eye may vary as much as that of their countenance ; of course, a pair of spectacles that might suit you, would not be adapted to another, whose eyes should require a similar aid.—What is the property of concave glasses ?

Charles. They cause the rays of light to diverge.

Tutor. Then for very round and globular

eyes, these will be useful, because if the eye is too convex, or crystalline $a b$ (Plate iv. Fig. 27.) too convex, the rays flowing from $r v$ will converge into a focus before they arrive at the retina, at z .

Charles. If the sight then depends on the positions produced on the retina, such a person will not see the object at all, because the image does not reach the retina.

Tutor. True: but at z the rays converge at another point, and pass on to the retina, where they will produce some sensations, but not distinct vision, because they are not brought to a focus there. To remedy this, the eye-glass $m n$ is interposed between the object and the eye, which causes the rays coming from the eye to *diverge*; and being more divergent when they enter the eye, it requires a very convex cornea or crystalline to bring them to a focus at the retina.

James. I have seen old people, when looking at an object, hold it at a good distance from their eyes.

Tutor. Because their eyes being too convex, the focus is thrown beyond the eye, and when they hold the object at a distance, to bring the focus z (Fig. 28.) to the retina.

Charles. Very short-sighted people look at objects close to their eyes.

Tutor. Yes, I once knew a young man who was apt, in looking at his paper, to rub

see what he had written with his pen. In case, bringing the object near the eye produces a similar effect to that produced by concave glasses: because the nearer the object is to the eye, the greater is the angle under which it is seen; that is, the extreme rays, of course, all the others, are made more divergent.

nes. I do not understand this.

tor. Well, let E be the eye, (Plate iv. Fig. 1.) and the object $a b$ seen at z , and also at x , z be the distance; will not the same object appear under different angles to an eye so situated?

nes. Yes, certainly $a E b$ will be larger than $c E d$, and will include it.

tor. Then the object being brought very near the eye, has the same effect as magnifying concave glasses, or of causing the rays to diverge; that is, though $a b$ and $c d$ are of the same size, yet $a b$ being nearest to the eye, will appear the largest.

nes. You say the eyes of old people become flat by age; is that the natural progress?

tor. It is; and therefore people who are short-sighted while young, will probably grow better when they grow old.

nes. That is an advantage denied to common eyes.

tor. But people blessed with common sight,

OPTICS.

uld be thankful for the benefit they derive from the
the young.

Charles. And I am sure we cannot too highly
estimate the science of optics, that has afforded
such assistance to defective eyes, in many
circumstances of life, would be unavailing
without them.

CONVERSATION XVIII.

Of the Rainbow.

Tutor. You have frequently seen a rainbow.

Charles. Oh, yes, and very often the two at the same time, one above the other. The
lower one is by far the most brilliant.

Tutor. This is, perhaps, the most beautiful
meteor in nature ; it never makes its appearance
but when a spectator is situated between
the sun and the shower. It is thus described
by Thomson :

—Reflected from yon eastern cloud,
Bestriding earth, the grand ethereal bow
Shoots up immense ; and every hue unfolds
In fair proportion, running from the red
To where the violet fades into the sky.

Here, awful Newton, the dissolving clouds
 Form, fronting on the sun, thy show'ry prism ;
 And to the sage-instructed eye unfold
 The various twine of light, by thee disclos'd
 From the white mingling maze.

James. Is a rainbow occasioned by the falling drops of rain ?

Tutor. Yes, it depends on the reflection and refraction of the rays of the sun by the falling drops.

Charles. I know now how the rays of the sun are *refracted* by water, but are they *reflected* by it also ?

Tutor. Yes ; water, like glass, reflects some rays, while it transmits or refracts others. You know the beauty of the rainbow consists in its colours.

James. Yes, "the colours of the rainbow" is a very common expression ; I have been told there are seven of them, but it is seldom that many can be clearly distinguished.

Tutor. Perhaps that is owing to your want of patience ; I will show you the colours first by means of the prism. If a ray of light *s* (Plate v. Fig. 31.) be admitted into a darkened room, through a small hole in the shutter *y*, its natural course is along the line to *d* ; but if a glass prism *a c* be introduced, the whole ray will be bent upwards, and if it be taken on any white surface as *M N*, it will form an ob-

long image $P T$, the breadth of which is the diameter of the hole in the screen.

Charles. This oblong is of different parts.

Tutor. These are the colours which are described by Dr. Darwin?

Next with illumin'd hands through prisms
Pleas'd they untwist the sevenfold thread
Or, bent in pencils by the lens, converge
To one bright point the silver hairs of

James. But how is the light separated by a *circular* hole in the window into an oblong?

Tutor. If the ray were of one colour it would be equally bent upwards, and form a small circular image. Since, however, the image or picture is oblong, it is formed of rays differently refracted, of which some are turned more outwards than others; the more refrangible, those which go to the upper part of the spectrum, the least refrangible, the intermediate, according to their more or less refrangibility, they are painted on the spectrum in the seven colours?

Charles. Yes, here is the violet, green, yellow, orange, and red.

Tutor. These colours will be

ful if a convex lens be interposed, at a proper distance, between the shutter and the prism.

James. How does this apply to the rainbow?

Tutor. Suppose Δ (Plate v. Fig. 32.) to be a drop of rain, and $s d$ a ray from the sun falling upon or entering it at d , will not go to c , but be refracted to n , where a part will go out, but a part also will be refracted to q , where it will go out of the drop, which acting like a prism, separates the ray into its primitive colours; the violet will be uppermost, the red lowermost.

Charles. Is it at any particular angle that these colours are formed?

Tutor. Yes, they are all at fixed angles; the least refrangible or red makes an angle with the solar incident ray, equal to little more than 42 degrees; and the violet or most refrangible ray, will make with the solar ray an angle of 40 degrees.

James. I do not understand which are these angles.

Tutor. The ray $s d$ would go to $f c$, therefore, the angle made with the red ray is $s f q$, and that made with the violet ray is $s c q$, the former $42^{\circ} 2'$, the latter $40^{\circ} 17'$.

Charles. Is this always the case be the sun either high or low in the heavens?

Tutor. It is; but the situation of the rainbow will vary accordingly as the sun is high or low, that is, the higher the sun, the lower will be the rainbow: a shower has been seen on a

mountain by a spectator in a valley, by a complete circular rainbow has been exhibited. *James.* And I once remember standing on Morant's Court Hill, in Kent, when there was a heavy shower, while the sun shone bright, and all the landscape beneath, to the horizon, seemed to be painted with the primary colours.

Tutor. I recollect this well: and perhaps some such scene Thomson alludes to: it was certainly the most beautiful one I ever beheld.

These, when the clouds distil the rosy shower,
Shine out distinct adown the watery bow:
While o'er our heads the dewy vision bends
Delightful, melting on the fields beneath.
Myriads of mingling dyes from these result,
And myriads still remain; infinite source
Of beauty, ever blushing, ever new.

Charles. You have not explained the difference of the upper or fainter bow.

Tutor. This is formed by two refractions and two reflections: suppose the ray Tr , entering the drop B at r . It is refracted at r , reflected at s , reflected again at t , and as it goes out at u , whence it proceeds separated, to the spectator at g . The colours are reversed; the angle formed by the red ray is 51° , and that formed by violet

James. Does the same thing happen in regard to a whole shower, as you have said in respect to the two drops?

ator. Certainly, and by the constant falling of the rain, the image is preserved constant and perfect. Here is the representation of the bow. (Plate v. Fig. 33.) The rays come from the direction *s* *A*, and the spectator stands at *E* with his back to the sun, or, in other words, he must be between the sun and the object.

This subject may be shown in another way; if a glass globule filled with water be hung sufficiently high before you, when the sun is behind, to appear red, let it descend gradually, and you will see in the descent all the other six colours follow one another. Artificial rainbows may be made with a common watering pot, but much better with a syringe fixed to an artificial fountain; and I have seen one by spouting up water from the mouth; it is often seen in cascades, in the foaming of the waves of the sea, in fountains, and even in the dew on the grass.

Dr. Langwith has described a rainbow, which he saw lying on the ground, the colours of which were almost as lively as those of the common rainbow. It was extended several hundred yards, and the colours were so strong, that it might have been seen much farther, if it had not been terminated by a bank, and the hedge of a field.

Rainbows have also been produced by the reflection of the sun's beams from a river: and

Mr. Edwards describes one which may have been formed by the exhalations from the London, when the sun had been set minutes.*

CONVERSATION XIX.

Of the Refracting Telescope.

Tutor. We now come to describe the structure of telescopes, of which there are two, viz. the *refracting* and the *reflecting* telescope.

Charles. The former or *refracting* telescope depends, I suppose, upon *lenses* for the refraction; and the *reflecting* telescope acts by the means of *mirrors*.

Tutor. These are the general principles which they are formed; and we shall defer the explanation of the *refracting* telescope. Here is one completely fitted up.

James. It consists of two tubes, and two glasses.

Tutor. The tubes are intended to be

* See Phil. Trans. Vols. VI. and L.

es, and to confine the boundary of the view. I therefore explain the principle by the wing figure (Plate v. Fig. 34.) in which is presented the eye $A B$, the two lenses $m n$, and the object $x y$. The lens $o p$, which is nearest to the object, is called the object-glass, and that $m n$ nearest to the eye is called the eye-glass.

Charles. Is the object-glass a double convex, the eye-glass a double concave?

Isaac. It happens so in this particular instance, but it is not necessary that the eye-glass should be concave; the object-glass must, however, in all cases, be convex.

Charles. I see exactly, from the figure, why the eye-glass is concave: for the convex lens converges the rays too quickly, and the focus that glass alone would be at e : and therefore the concave is put near the eye, to make the rays diverge so much as to throw them to the retina before they come to a focus.

Isaac. But that is not the only reason: by bringing to a focus at e , the image is very small, in comparison of what it is when the image is formed on the retina, by means of the concave.

Can you, James, explain the reason of the lines which you see in the figure?

James. I think I can:—there are two pencils of rays flowing from the extremities of the object, which is the object to be viewed. The pencils of the pencil flowing from x , go on di-

verging till they reach the convex when they will be so refracted by through the glass, as to converge, and the point x . Now the same may be said of a pencil of rays which comes from y ; in short, of all the pencils of rays flowing from the object between x and y . So that the tip of the arrow would, by the convex glass, be formed at x .

Tutor. And what would happen if there was no other glass?

James. The rays would cross each other and be divergent, so that when they got to the retina, there would be no distinct image but every point as x or y , would be spread out in a large space, and the image would be indistinct. To prevent this, the concave lens $m\ n$ is now proposed; the pencil of rays which would have converged at x , by the convex glass, will now be made to diverge, so as not to come to a focus before they arrive at the retina: and the pencil of rays which would, by the convex glass, have converged to a point at y , will, by the interposition of the concave lens, be made to diverge so much that it will throw the focus of the rays to b instead of x . By this means, the image of the object is rendered distinct.

Tutor. Can you tell the reason why the object is required to be drawn out more or less for different persons?

Charles. The tubes are to be adjusted

throw the focus of rays exactly on the eye; and as some eyes are more convex than others, the length of the focus will vary in different persons, and, by sliding the tube up or down, this object is obtained.

tor. Refracting telescopes are used chiefly for viewing the terrestrial objects; two things, therefore, are requisite in them; the first is, that it should show objects in an upright position—that is, in the same position as we see them without glasses; and the second is, that it should afford a large *field of view*.

nes. What do you mean, sir, by a field of

tor. All that part of landscape which may be seen at once, without moving the eye or instrument. Now, in looking on the figure again, you will perceive that the concave lens throws a number of the rays beyond the pupil *c* of the telescope to the iris on both sides, but those only which are visible, or go to form an image, which pass through the pupil; and therefore, by a telescope made in this way, the middle part of the object is only seen, or, in other words, the prospect is by it very much diminished.

nrles. How is that remedied?

tor. By substituting a double convex eyeglass *h* (Plate v. Fig. 35.) instead of the concave one. Here the focus of the double convex is at *E*, and the glass *g h* must be so much more convex than *o p*, as that its focus may be

also at E : for then the rays flowing from the object $x y$, and passing through the object-glass $o p$, will form the inverted image $m E$ by interposing the double convex $g h$, and it is thrown on the retina, and it is seen under the large angle $D E C$, that is, the image will be magnified to the size $C E D$.

James. Is not the image of the object seen by the telescope inverted?

Tutor. Yes, it is: for you see the image on the retina stands in the same position as the object; but we always see things by their images inverted: and, therefore, what is seen by telescopes constructed as this is seen by the eye appear inverted to the spectator, which is an unpleasant circumstance with regard to terrestrial objects; it is on that account chiefly avoided for celestial observations.

Charles. Is there any rule for calculating the magnifying power of this telescope?

Tutor. It magnifies in proportion as the distance of the object-glass is greater than the focal distance of the eye-glass. The magnifying power of the object-glass is ten times that of the eye-glass only a single telescope magnifies the *diameter* of the object ten times: and the *whole surface* of the object will be magnified a hundred times.

Charles. Will a small object, as a signet-ring, for instance, appear a hundred times

through this telescope than it would by the naked eye?

Tutor. Telescopes, in general, represent terrestrial objects to be *nearer* and not *larger*: thus, looking at the silver penny a hundred yards distant, it will not appear to be larger, but at the distance only of a single yard.

James. Is there no advantage gained, if the focal distance of the eye-glass, and of the object-glass, be equal?

Tutor. None; and therefore in telescopes of this kind we have only to increase the focal distance of the object-glass, and to diminish the focal distance of the eye-glass, to augment the magnifying power to almost any degree.

Charles. Can you carry this principle to any extent?

Tutor. Not altogether so: an object-glass of ten feet focal distance, will require an eye-glass whose focal distance is rather more than two inches and a half: and an object-glass with a focal distance of a hundred feet, must have an eye-glass whose focus must be about six inches from it. How much will each of these glasses magnify?

James. Ten feet divided by two inches and a half, give for a quotient forty-eight: and a hundred feet divided by six inches, give two hundred, so that the former magnifies 48 times, and the latter 200 times.

Tutor. Refracting telescopes for viewing ter-

restrial objects, in order to show them in their natural posture, are usually constructed with one object-glass, and three eye-glasses, the focal distances of these last being equal.

James. Do you make use of the same rule in calculating the magnifying power of a telescope constructed in this way, as you do of the last?

Tutor. Yes; the three glasses next to each other having their focal distances equal, the magnifying power is found by dividing the focal distance of the object-glass by the focal distance of one of the eye-glasses. We have said as much on the subject as is necessary for the present plan.

Charles. What is the construction of the opera-glasses, that are so much used at the theatre?

Tutor. The opera-glass is nothing more than a short refracting telescope.

The *night* telescope is only about 12 inches long; it represents objects inverted, and dimly lightened, but not greatly magnified. It is used to discover objects, not very distant, but which cannot otherwise be seen for want of light.

CONVERSATION XX.

Of Reflecting Telescopes.

tor. This is a telescope of a different kind, called a *reflecting* telescope.

irles. What advantages does the reflecting telescope possess over that which you described yesterday?

tor. The great inconvenience attending reflecting telescopes is their length, and on that account they are not very much used when high powers are required. A reflector of six feet will magnify as much as a refractor of a hundred feet.

irles. Are these, like the refracting telescopes, made in different ways?

tor. They were invented by Sir I. Newton, but have been greatly improved since his time. The following figure (Plate vi. Fig. 36.) will lead to a description of one of those most commonly used. You know that there is a great similarity between *convex lenses* and *concave mirrors*.

irles. They both form an inverted focal image of any remote object, by the convergence of a pencil of rays.

tor. In instruments, the exhibitions of

which are the effects of reflection, the concave mirror is substituted for the convex lens. *T* (Fig. 36.) represents the large tube, and *t t* the small tube of the telescope, at one end of which is *D F*, a concave mirror, with a hole in the middle at *P*, the principal focus of which is a *I K*; opposite to the hole *P*, is a mirror *L*, concave towards the great one; it is fixed on a strong wire *M*, and may, by means of a long screw on the outside of the tube, be made to move backwards or forwards. *A B* is a remote object: from which rays will flow to the great mirror *D F*.

James. And I see you have taken only two rays of a pencil from the top, and two from the bottom.

Tutor. And in order to trace the progress of the reflections and refractions, the upper ones are represented by full lines, the lower ones by dotted lines. Now the rays at *c* and *E* falling upon the mirror at *D* and *F*, are reflected, and form an inverted image at *m*.

Charles. Is there any thing there to receive the image?

Tutor. No: and therefore they go on towards the reflector *L*, the rays from different parts of the object crossing one another a little before they reach *L*.

James. Does not the hole at *P* tend to distort the image?

Tutor. Not at all; the only defect is, tha

re is less light. From the mirror L the rays are reflected nearly parallel through P , there they have to pass the plano-convex lens R , which causes them to converge at $a b$, and the image is now painted in the small tube near the eye.

Charles. What is the other plano-convex lens for?

Tutor. Having by means of the lens R , and two concave mirrors, brought the image of object so nigh as at $a b$, we only want to magnify the image.

James. This, I see, is done by the lens s .

Tutor. It is, and will appear as large as $c d$, that is, the image is seen under the angle $c f d$.

Charles. How do you estimate the magnifying power of the reflecting telescope?

Tutor. The rule is this: "Multiply the focal distance of the large mirror by the distance the small mirror from the image m : then multiply the focal distance of the small mirror by the focal distance of the eye-glass; and divide these two products by one another, and the quotient is the magnifying power."

James. It is not likely that we should know these in any instrument we possess.

Tutor. The following, then, is a method of finding the same thing by experiment. "Observe at what distance you can read any book with the naked eye, and then remove the book to the farthest distance at which you can dis-

tinctly read by means of the telescope, and divide the latter by the former."

Charles. Has not Dr. Herschel a very large reflecting telescope?

Tutor. He has made many, but the tube of the grand telescope is nearly 40 feet long, and four feet ten inches in diameter. The concave surface of the great mirror is 48 inches, of polished surface, in diameter, and it magnifies 6000 times. This noble instrument cost the Doctor four years' severe labour: it was finished August 28, 1789, on which day was discovered the sixth satellite of Saturn.

Delighted Herschel, with reflected light,
Pursues his radiant journey through the night,
Detects new guards, that roll their orbs afar,
In lucid ringlets round the Georgian star.

DARWIN.

CONVERSATION XXI.

Of the Microscope—Its Principle—Of the Single Microscope—Of the Compound Microscope—Of the Solar Microscope.

Tutor. We are now to describe the microscope, which is an instrument for viewing very

small objects. You know that, in general, persons who have good sight cannot distinctly view an object at a nearer distance than about six inches.

Charles. I cannot read a book at a shorter distance than this; but if I look through a small hole made with a pin or needle in a sheet of my own paper, I can read at a very small distance indeed.

Tutor. You mean, that the letters appear, in that case, very much magnified, the reason of which is, that you are able to see at a much shorter distance in this way, than you can without the intervention of the paper. Whatever instrument, or contrivance, can render minute objects visible and distinct, is properly a microscope.

James. If I look through the hole in the paper, at the distance of five or six inches from the print, it is not magnified.

Tutor. The object must be brought near, to increase the angle by which it is seen; this is the principle of all microscopes, from the single lens to the most compound instrument. *A* (Plate . Fig. 37.) is an object not clearly visible at less distance than *A B*; but if the same object be placed in the focus *c* (Fig. 38.) of the lens *D*, the rays which proceed from it will become parallel, by passing through the said lens, and therefore the object is distinctly visible to the eye at *E*, placed any where before the lens.

There are three distinctions in microscopes, the single, the compound, and the solar.

Charles. Does the single microscope consist only of a lens?

Tutor. By means of a lens a great number of rays proceeding from a point are united in the same sensible point, and as each ray carries with it the image of the point from whence it proceeded, all the rays united must form an image of the object.

James. Is the image brighter in proportion as there are more rays united?

Tutor. Certainly: and it is more distinct in proportion as their natural order is preserved. In other words, a single microscope or lens removes the confusion that accompanies objects when seen very near by the naked eye; and it magnifies the diameter of the object, in proportion as the focal distance is less than the limit of distinct vision, which we may reckon from about six to eight inches.

Charles. If the focal distance of a reading-glass be four inches, does it magnify the diameter of each letter only twice?

Tutor. Exactly so: but the lenses used in microscopes are often not more than $\frac{1}{4}$ or $\frac{1}{8}$ or even $\frac{1}{16}$ part of an inch radius.

James. And in a double convex the focal distance is always equal to the radius of convexity.

Tutor. Then tell me how much lenses of $\frac{1}{4}$, $\frac{1}{8}$, and $\frac{1}{16}$ of an inch will each magnify?

James. That is readily done ; by dividing 8 inches, the limit of distinct vision, by $\frac{1}{4}$, $\frac{1}{8}$, and $\frac{1}{16}$.

Charles. And to divide a whole number, as 8, by a fraction, as $\frac{1}{4}$, &c. is to multiply the said number by the denominator of the fraction : of course, 8 multiplied by 4, gives 32 ; that is, the lens, whose radius is a $\frac{1}{4}$ of an inch, magnifies the diameter of the object 32 times.

James. Therefore the lenses of which the radii are $\frac{1}{8}$ and $\frac{1}{16}$ will magnify as 8 multiplied by 8, and 8 multiplied by 20 ; that is, the former will magnify 64 times, the latter 160 times, the diameter of an object.

Tutor. You see, then, that the smaller the lens, the greater its magnifying power. Dr. Hooke says, in his work on the microscope, that he has made lenses so small as to be able, not only to distinguish the particles of bodies a million times smaller than a visible point, but even to make those visible of which a million times a million would hardly be equal to the bulk of the smallest grain of sand.

Charles. I wonder how he made them.

Tutor. I will give you his description : he first took a very narrow and thin slip of clear glass, melted it in the flame of a candle or lamp, and drew it out into exceedingly fine threads. The end of one of these threads he melted again in the flame till it run into a very small drop, which, when cool, he fixed in a thin plate of

metal, so that the middle of it might be directed over the centre of an extremely small hole made in the plate. Here is a very convenient simple microscope.

James. It does not seem, at first sight, simple as those which you have just now described.

Tutor. *A* (Fig. 39.) is a circular piece of brass, it may be made of wood, ivory, &c. the middle of which is a very small hole, in this is fixed a small lens, the focal distance of which is *AD*, at that distance is a pair of pliers *DE* which may be adjusted by the sliding screw and opened by means of two little studs *a* with these any small object may be taken up and viewed with the eye placed at the other focus of the lens at *F*, to which it will appear magnified as at *IM*.

Charles. I see by the joint it is made to fold up.

Tutor. It is; and may be put into a case, and carried about in the pocket, without any inconvenience or inconvenience. Let us now look at the double or compound microscope.

James. How many glasses are there in this?

Tutor. There are two; and the construction of it may be seen by this figure; *cd* (Fig. 40) is called the object-glass, and *ef* the eye-glass. The small object *ab* is placed a little farther from the glass *cd* than its principal focus, so that the pencils of rays flowing from the different

nts of the object, and passing through
 is, may be made to converge and unite
 any points between g and h , where the
 of the object will be formed. This image
 ed by the eye-glass ef , which is so placed
 e image $g h$ may be in the focus, and
 at about an equal distance on the other
 e rays of each pencil will be parallel af-
 ing out of the eye-glass, as at e and f , till
 me to the eye at k , by the humours of
 hey will be converged and collected into
 on the retina, and form the large invert-
 ed $A B$.

les. Pray, sir, how do you calculate the
 ving power of this microscope?

r. There are two proportions, which,
 ound, are to be multiplied into one an-
 (1.) As the distance of the image from
 ct-glass is *greater* than its distance from
 -glass; and, (2.) as the distance from
 ect is *less* than the limit of distinct

ple. If the distance of the image from
 ct-glass be four times greater than from
 -glass, the magnifying power of four is

ince gives the following rule for finding the linear
 g power of a compound microscope: "It is equal
 ast distance of distinct vision, multiplied by the
 of the image from the object-glass, divided by the
 of the object from the object-glass, multiplied by
 length of the eye-glass."

gained: and if the focal distance of the eye-glass be one inch, and the distance of distinct vision be considered at seven inches, the magnifying power of seven is gained, and 7 multiplied by 4 gives 28; that is, the diameter of the object will be magnified 28 times, and the surface will be magnified 784 times.

James. Do you mean that an object will through such a microscope, appear 784 times larger than by the naked eye?

Tutor. Yes, I do; provided the limit of distinct vision be seven inches; but some persons who are short-sighted, can see as distinctly at five or four inches, as another can at seven or eight: to the former the object will not appear so large as to the latter.

Ex. 2. What will a microscope of this kind magnify to three different persons, whose eyes are so formed as to see distinctly at the distance of 6, 7, and 8 inches by the naked eye; supposing the image of the object-glass to be five times as distant as from the eye-glass, and the focal distance of the eye-glass be only the tenth part of an inch?

Charles. As five is gained by the distance between the glasses, and 60, 70, and 80, by the eye-glass, the magnifying powers will be as 300, 350, and 400.

James. How is it 60, 70, and 80, are gained by the eye-glass?

Charles. Because the distances of distinct v

sion are put at 6, 7, and 8 inches, and these are to be divided by the focal distance of the eye-glass, or by $\frac{1}{8}$; but to divide a whole number by a fraction, we must multiply that number by the denominator, or lower figure in the fraction: therefore the power gained by the distance between the two glasses, or 5, must be multiplied by 60, 70, or 80. And the surface of the object will be magnified in proportion to the square of 300, 350, or 400, that is as 90,000, 122,500, or 160,000.

Tutor. We now come to the solar microscope, which is by far the most entertaining of them all, because the image is much larger, and being thrown on a sheet, or other white surface, may be viewed by many spectators at the same time, without any fatigue to the eye. Here is one fixed in the window-shutter, but I can explain its construction best by a figure.

James. There is a looking-glass on the outside of the window.

Tutor. Yes, the solar microscope consists (Plate VI. Fig. 42.) of a looking-glass *s o* without, the lens *a b* in the shutter *d u*, and the lens *n m* within the dark room. These three parts are united to, and in a brass tube. The looking-glass can be turned by the adjusting screw, so as to receive the incident rays of the sun *s s*, and reflect them through the tube into the room. The lens *a b* collects those rays into a focus at *n m*, where there is another magnifier;

here, of course, the rays cross, and diverge to the white screen on which the image of the object will be painted.

Charles. I see the object is placed a little behind the focus.

Tutor. If it were in the focus, it would be burnt to pieces immediately. The magnifying power of this instrument depends on the distance of the sheet or white screen; perhaps about 10 feet is as good a distance as any. You perceive that the size of the image is to that of the object as the distance of the former from the lens nm , is to that of the latter.

James. Then the nearer the object to the lens, and the farther the screen from it, the greater the power of this microscope.

Tutor. You are right, and if the object be only half an inch from the lens, and the screen nine feet, the image will be 46,656 times larger than the object: do you understand this?

Charles. Yes, the object being only half an inch from the lens, and the image nine feet, or one hundred and eight inches, or two hundred and sixteen half inches, the diameter of the image will be two hundred and sixteen times larger than the diameter of the object, and this number multiplied into itself will give 46,656

Tutor. This instrument is calculated only to exhibit transparent objects, or such as the light can pass through in part. For opaque objects a different microscope is used: and, indeed

are an indefinite number of microscopes,
 of them all, we may say, though in differ-
 ences :

The artificial convex will reveal
 the forms diminutive that each conceal;
 some so minute, that, to the one extreme,
 some might a vast Leviathan would seem;
 at yet of organs, functions, sense partake
 equal with animals of larger make.
 Curious limbs and clothing they surpass
 far the comeliest of the bulky mass.
 World of beauties! that through all this frame
 Creation's grandest miracles proclaim.

BROWNE.

CONVERSATION XXII.

: Camera Obscura, Magic Lantern, and Multiplying
 Glass.

tor. We shall now treat upon some miscel-
 laneous subjects; of which the first shall be the
Camera Obscura.

urles. What is a camera obscura?

tor. The meaning of the term is a dark-
 chamber: the construction of it is very
 simple, and will be understood in a moment by

F

you, who know the properties of the convex lens.

A convex lens placed in a hole of a window shutter, will exhibit, on a white sheet of paper placed in the focus of the glass, all the objects on the outside, as fields, trees, men, houses, &c. in an inverted order.

James. Is the room to be quite dark, except the light which is admitted through the lens?

Tutor. It ought to be so; and, to have a very interesting picture, the sun should shine upon the objects.

James. Is there no other kind of camera obscura?

Tutor. A portable one may be made with a square box, in one side of which is to be fixed a tube, having a convex lens in it: within the box is a plain mirror, reclining backwards from the tube, in an angle of forty-five degrees.

Charles. On what does this mirror reflect the image of the object?

Tutor. The top of the box is a square of unpolished glass, on which the picture is formed. And if a piece of oiled paper be stretched on the glass, a landscape may be easily copied; or the outline may be sketched on the rough surface of the glass.

James. Why is the mirror to be placed at an angle of 45 degrees exactly?

Tutor. The image of the objects would naturally be formed at the back of the box oppo-

the lens ; in order, therefore, to throw it up, the mirror must be so placed that the incident ray shall be perpendicular to the end. In the box, according to its original position, the top is at right angles to the end, but it is now turned at an angle of 90 degrees, therefore the mirror is put at half 90, or 45 degrees.

Q. Now the incident rays falling upon the mirror which declines to an angle of 45 degrees will be reflected at an equal angle of 45 degrees, which is the angle that the glass top of the box bears with respect to the mirror.

A. If I understand you clearly, had the lens been placed at the end of the box, or at the top of it, the rays would have been reflected to the lens ; and none would have proceeded to the top of the box.

A. True : in the same manner as when a person stands before a looking-glass, another person on the side of the room cannot see his image in the glass, because the rays flowing from the person to the looking-glass are thrown back to the person again ; but let each person stand on the opposite side of the room, while the glass is in the middle of the end of it, they will both stand at an angle of 45 degrees, with regard to the end of the box, and rays from each will be reflected to the lens.

Q. Is the tube fixed in this machine ?

A. No ; it is made to draw out, or push in, to adjust the distance of the convex lens. III.—L

glass from the mirror, in proportion to the distance of the outward objects, till they are distinctly painted on the horizontal glass.

James. Will you now explain the structure of the magic-lantern, which has long afforded occasional amusement?

Tutor. This little machine consists, as you know, of a sort of tin box; within which is a lamp or candle: the light of this passes through a great plano-convex lens, placed in a tube fixed in the front. This strongly illuminates the objects which are painted on slips of glass placed before the lens in an inverted position. A sheet, or other white surface, is placed to receive the images.

Charles. Do you invert the glasses on which the figures are drawn, in order that the images of them may be erect?

Tutor. Yes: and the illumination is thereby greatly increased, and the effect much more powerful, by placing a concave mirror behind the back of the lamp.

Charles. Did you not tell us that the *Phantasmagoria*, which we saw at the Lyceum, was a species of the magic-lantern?

Tutor. There is this difference between the common magic-lanterns, the figures are painted on transparent glass, consequently the image on the screen is a circle of light, having the figure or figures on it; but in the *Phantasmagoria*, all the glass is made opaque, except

ly, which being painted in transparent the light shines through it, and no light is upon the screen but what passes the figure.

. But there was no sheet to receive the

. No : the representation was thrown on screen of silk placed between the spectator and the lantern.

23. What caused the images to appear coming and receding?

. It is owing to removing the lantern from the screen, or bringing it nearer or farther, the size of the image must increase, or decrease, if the lantern is carried back, because the rays form the shape of a cone, and as no part of the screen is visible, the figure appears to be in the air, and to move farther off when the lantern is smaller, and to come nearer as it is brought nearer in size.

. Here is another instrument, the construction of which you promised to explain : the multiplying glass.

. One side of this glass is cut into many small surfaces, and in looking at an object, through it, you will see not one only, but as many as the glass contains small surfaces.

draw a figure to illustrate this : let it be (Fig 42.) $A i B$ represent a glass, flat at one end next the eye H , and cut into three

distinct surfaces on the opposite side, as *A d B*. The object *c* will not appear magnified but as rays will flow from it to all parts of glass, and each plane surface will refract rays to the eye, the same object will appear to the eye in the direction of the rays, whether it through each surface. Thus a ray falling perpendicularly on the middle surface will suffer no refraction, but show the object its true place at *c*: the ray from *c b*, falling obliquely on the plane surface *A b*, will be refracted in the direction *b e*, and on leaving the surface at *e*, it will pass to the eye in the direction *e f* and therefore it appears at *E*; and the ray from *c g* will, for the same reason, be refracted to the eye in the direction *B H*, and the object *c* will appear also in *B*.

If, instead of three sides, the glass has been cut into 6, or 20, or any other number, the object would have appeared 6, 20, &c. different objects differently situated.

MAGNETISM.

CONVERSATION XXIII.

Of the Magnet: its Properties: useful to Mariners, and others; Iron rendered Magnetic; Properties of the Magnet.

TUTOR. You see this dark brown mineral body, it is almost black, and you know it has the property of attracting needles and other small iron substances.

James. Yes, it is called a load-stone, leading-stone, or magnet; we have often been amused with it: but you told us that it possessed a much more important property than that of attracting iron and steel.

Tutor. This is what is called the *directive property*, by which mariners are enabled to conduct their vessels through the mighty ocean, out of the sight of land: by the aid of this, miners are guided in their subterranean inquiries, and the traveller through deserts, otherwise impassable.

Charles. Were not mariners unable to make long and very distant voyages till this property of the magnet was discovered?

Tutor. Till then, they contented themselves with mere coasting voyages; seldom trusting themselves from the sight of land.

James. How long is it since this property of the magnet was first known?

Tutor. About five hundred years; and it is not possible to ascertain, with any degree of precision, to whom we are indebted for this great discovery.

Charles. You have not told us in what the discovery consists.

Tutor. When a magnet, or a needle rubbed with a magnet, is freely suspended, it will always, and in all places, stand nearly north and south.

Charles. Is it known which end points to the north, and which to the south?

Tutor. Yes: or it would be of little use: each magnet, and each needle, or other piece of iron, that is made an *artificial* magnet by being properly rubbed with the *natural* magnet, has a north end and a south end, called the *north* and *south poles*: to the former a mark is placed, for the purpose of distinguishing it.

James. Then if a ship were to make a voyage to the north, it must follow the direction which the magnet takes.

Tutor. True: and if it were bound a westerly course, the needle always pointing north, the ship must keep in a direction at right angles to

the needle. In other words, the direction of the needle must be across the *ship*.

Charles. Could not the same object be obtained by means of the pole star?

Tutor. It might, in a considerable degree, provided you could always ensure a fine clear sky; but what is to be done in cloudy weather, which, in some latitudes, will last for many days together?

Charles. I did not think of that.

Tutor. Without the use of the magnet, no persons could have ventured upon such voyages as those to the East Indies, and other distant parts; the knowledge, therefore, of this instrument, cannot be too highly prized.

James. Is that a magnet which is fixed to the bottom of the globe, and by means of which we set the globe in a proper direction with regard to the cardinal points, north, south, east, and west.

Tutor. That is called a compass, the needle of which being rubbed by the natural or real magnet, becomes possessed of the same properties as those which belong to the magnet itself.

Charles. Can any iron and steel be made magnetic?

Tutor. They may; but steel is the most proper for the purpose. Bars of iron thus prepared are called *artificial magnets*.

James. Will these soon lose the properties thus obtained?

Tutor. Artificial magnets will retain their properties almost any length of time, and since they may be rendered more powerful than natural ones, and can be made of any form, they are generally used, so that the natural magnet is kept as a curiosity.

Charles. What are the leading properties of the magnet?

Tutor. (1.) A magnet attracts iron. (2.) When placed so as to be at liberty to move in any direction, its north end points to the north pole, and its south end to the south pole: that is called the *polarity* of the magnet. (3.) When the *north* pole of one magnet is presented to the *south* pole of another, they will attract one another. But if the two *south*, or the two *north* poles, are presented to each other, they will repel. (4.) When a magnet is so situated as to be at liberty to move any way, the two poles of it do not lie in a horizontal direction, it inclines one of its poles towards the horizon, and of course, elevates the other pole above it; this is called the *inclination* or *dipping* of the magnet. (5.) Any magnet may be made to impart its properties to iron and steel.

CONVERSATION XXIV.

Magnetic Attraction and Repulsion.

tor. Having mentioned the several properties of the magnet or loadstone, I intend, at this time to enter more particularly into the nature of magnetic attraction and repulsion.—Here is an iron bar, eight or nine inches long, rendered magnetic, and on that account it is now an artificial magnet: I bring a small piece of iron within a little distance of one of the poles of the magnet, and you see it is attracted and drawn to it.

urles. Will not the same effect be produced if the iron be presented to any other part of the magnet?

tor. The attraction is strongest at the poles, and it grows less and less in proportion to the distance of any part from the poles, so that in the middle, between the poles, there is no attraction, as you shall see by means of this needle.

nes. When you held the needle near the pole of the magnet, the magnet moved to that, and it looks as if the needle attracted the mag-

Tutor. You are right: the attraction is tual, as is evident from the following experiment. I place this small magnet on a piece of cork, and the needle on another piece, and let them float on water, at a little distance from each other, and you observe that the magnet moves towards the iron, as much as the needle moves towards the magnet.

Charles. If two magnets were put in this situation, what would be produced?

Tutor. If poles of the same name, that is two north, or the two south, be brought together, they will repel one another; but if north and south pole be presented, the kind of attraction will be visible, as there is no obstacle between the magnet and needle.

James. Will there be any attraction or repulsion if other bodies, as paper, or thin pieces of wood, be placed between the magnets, or between the magnet and iron?

Tutor. Neither the magnetic attraction nor repulsion is in the least diminished, or in any way affected by the interposition of any kind of bodies, except iron. Bring the magnets together within the attracting or repelling distance, and hold a slip of wood between them: you will see that they both come to the wood.

Charles. You said that iron was more easily rendered magnetic than steel, does it retain its magnetic properties as long too?

Tutor. If a piece of soft iron, and a piece of

hard steel, be brought within the influence of a magnet, the iron will be most forcibly attracted, but it will almost instantly lose its acquired magnetism, whereas the hard steel will preserve it a long time.

James. Is magnetic attraction and repulsion at all like what we have sometimes seen in electricity?

Tutor. In some instances there is a great similarity: *Ex.* I tie two pieces of soft wire (Plate VIII. Fig. 28.) each to a separate thread, which join at top, and let them hang freely from a hook α . If I bring the marked or north end of a magnetic bar just under them, you will see the wires repel one another, as they are shown in the figure hanging from α .

Charles. Is that occasioned by the repelling power which both wires have acquired in consequence of being both rendered magnetic with the same pole?

Tutor. It is: and the same thing would have occurred if the south pole had been presented instead of the north.

James. Will they remain long in that position?

Tutor. If the wires are of very soft iron they will quickly lose their magnetic power; but if steel wires be used, as common sewing needles, they will continue to repel each other, after the removal of the magnet.

Ex. II. I lay a sheet of paper flat upon a ta-
VOL. III.—M

ble, and strew some iron filings upon it. I now lay this small magnet (Fig. 29.) among them and give the table a few gentle knocks, so as to shake the filings, and you observe in what manner they have ranged themselves about the magnet.

Charles. At the two ends or poles, the particles of iron form themselves into lines, a little sideways; they bend, and then form complete arches, reaching from some point in the northern half of the magnet to some other point in the southern half.—Pray how do you account for this?

Tutor. Each of the particles of iron, by being brought within the sphere of the magnetic influence, becomes itself magnetic, and possessed of two poles, and consequently disposes itself in the same manner as any other magnet would do, and also attracts with its extremities the contrary poles of other particles.

Ex. III. If I shake some iron filings through a gauze sieve, upon a paper that covers a bar magnet, the filings will become magnets, and will be arranged in beautiful curves.

James. Does the polarity of the magnet reside only in two ends of its surface?

Tutor. No: one half of the magnet is possessed of one kind of polarity, and the other of the other kind; but the ends, or poles, are those points in which that power is the strongest.

r. A line drawn from one pole to the other is called the axis of the magnet.

CONVERSATION XXV.

Method of making Magnets—Of the Mariner's Compass.

Mr. I have already told you that artificial magnets, which are made of steel, are now generally used in preference to the real magnet, because they can be procured with greater ease, can be varied in their form more easily, and can communicate the magnetic virtue more fully.

Ques. How are they made?

Mr. The best method of making artificial magnets is to apply one or more powerful magnet-pieces of hard steel, taking care to apply the north pole of the magnet or magnets to that extremity of the steel which is required to be the south pole, and to apply the south pole of the magnet to the opposite extremity of the steel.

Ques. Has a magnet, by communicating its

versed.

Charles. Will steel produce the same effect?

Tutor. It will not; the iron must be in a perpendicular position, and hence bars of iron that have been in a perpendicular position, are generally made magnetic, as fire irons, bars of iron, &c.—If a long piece of hard iron be heated, and then left to cool in the direction of the magnetic line, it usually becomes magnetic.

Striking an iron bar with a hammer, or filing it with a file, while held in the magnetic line, renders it magnetic. An electric spark, or lightning, frequently renders iron magnetic.

James. An artificial magnet, you say, is often more powerful than the real one. Can it communicate a stronger power than it possesses?

Tutor. Certainly not: but two or three magnets, joined together, may communicate a stronger power than one.

or. Yes; very powerful magnets may be made by first constructing several weak magnets and then joining them together to form a single one, and to act more powerfully upon pieces of steel.

The following methods are among the best for making artificial magnets :

Place two magnetic bars **A** and **B** (Fig. 25.) in a line, so that the north or marked end of **A** shall be opposite to the south end of the bar **B**, but at such a distance, that the magnet **A** when touched, may rest with its marked end to the unmarked end of **B**, and its unmarked end to the marked end of **A**. Now apply the north end of the magnet **L**, and the south end of the magnet **D** to the middle of **C**, the opposite ends being directed as in the figure. Draw **L** and **D** along the bar **C**, one towards **A**, the other towards **B**, preserving the same elevation : recede **L** and **D** a foot or more from the bar when they reach the ends, then bring the north and south ends of these magnets together, and apply them to the middle of the bar **C** as before : the process is to be repeated five or six times, then turn the bar, and touch the other three sides in the same way, and with care the bar will acquire a strong fixed magnetism.

Upon a similar principle, two bars **A** **B**, (Fig. 26.) may be rendered magnetic. They are supported by two bars of iron, and are so placed that the marked end **B** may

be opposite to the unmarked end *n* ; then the two attracting poles *a* *i*, on the ends *A* *B*, as in the figure, moving them slowly it ten or fifteen times. The same operation to be performed on *c* *D*, having first reversed the poles of the bars, and then on the other faces of the bars ; and the business is finished.

The touch thus communicated may be increased by rubbing the different faces of the bars with sets of magnetic bars, disposed as in Fig. 27.

James. I suppose all the bars should be smooth.

Tutor. Yes, they should be well polished, the sides and ends made quite flat, and the corners quite square, or right angles.

There are many magnets made in the shape of horse-shoes ; these are called horse-shoe magnets, and they retain their power very long, by taking care to join a piece of iron to the ends as soon as it is done with.

Charles. Does that prevent its power from escaping ?

Tutor. It should seem so ; the power of the magnet is even increased by suffering a piece of iron to remain attached to one or both of its poles. Of course a single magnet should never be thus left.

James. How is magnetism communicated to compass needles ?

Tutor. Fasten the needle down on a board, and draw magnets about six inches long, in each hand, from the centre of the needle outwards; then raise the bars to a considerable distance from the needle, and bring them perpendicularly down on its centre, and draw them over again, and repeat this operation about twenty times, and the ends of the needle will point to the poles contrary to those that touched them.

Charles. I remember seeing a compass, when I was on board the frigate that lay off Worthing; the needle was in a box, with a glass over it.

Tutor. The mariner's compass consists of the box, the card or fly, and the needle. The box is circular, and is so suspended as to retain its horizontal position in all the motions of the ship. The glass is intended to prevent any motion of the card by the wind. The card or fly moves with the needle, which is very nicely balanced on a centre. It may, however, be noticed, that a needle which is accurately balanced before it is magnetized, will lose its balance by being magnetized, on account of what is called the *dipping*, therefore a small weight, or moveable piece of brass, is placed on one side of the needle, by the shifting of which the needle will always be balanced.

CONVERSATION XXVI.

Of the Variation of the Compass.

Charles. You said, I think, that the magnet pointed *nearly* north and south; how much does it differ from that line?

Tutor. It rarely points exactly north and south, and the *deviation* from that line is called the *variation of the compass*, which is said to be east or west.

James. Does this differ at different times?

Tutor. It does; and the variation is very different in different parts of the world. The variation is not the same now that it was half a century ago, nor is it the same now at London that it is at Bengal or Kamtschatka. The needle is continually traversing slowly towards the east and west.

This subject was first attended to by Mr. Burrows, about the year 1580, and he found the variation then, at London, about $11^{\circ} 11'$ east. In the year 1657, the needle pointed due north and south: since which the variation has been gradually increasing towards the west, and in the year 1803, it was equal to something more than 24° west, and was then advancing towards the same quarter.

Charles. That is at the rate of something more than ten minutes each year.

Tutor. It is ; but the annual variation is not regular ; it is more one year than another. It is different in the several months, and even in the hours of the day.

James. Then if I want to set a globe due north and south, to point out the stars by, I must move it about, till the needle in the compass points to 24° west.

Tutor. Just so : and mariners, knowing this, are as well able to sail by the compass, as if it pointed due north.

Charles. You mentioned the property which the needle had of *dipping*, after the magnetic fluid was communicated to it : is that always the same ?

Tutor. It probably is, at the same place : it was discovered by Robert Norman, a compass-maker, in the year 1576, and he then found it to dip nearly 72° , and from many observations made at the Royal Society, it is found to be the same.

James. Does it differ in different places ?

Tutor. Yes. In the year 1773, observations were made on the subject, in a voyage toward the north pole, and from these it appears that

In latitude	$60^{\circ} 18'$	the dip was	$75^{\circ} 0'$
_____	70 45	_____	77 52
_____	80 12	_____	81 52
_____	80 27	_____	82 2½

I will show you an experiment on this subject. Here is a magnetic bar, and a small dipping needle: if I carry the needle, suspended freely on a pivot, from one end of the magnetic bar to the other, it will, when directly over the south pole, settle directly perpendicular to the bar, the north end being next to the south pole. As the needle is moved, the dip grows less and less, and when it comes to the magnetic centre it will be parallel to the bar; afterwards the south end of the needle will dip, and when it comes directly over the north pole, it will again be perpendicular to the bar.

The following facts are deserving of recollection.

1. Iron is the only body capable of being affected by magnetism.

2. Every magnet has two opposite points called *poles*.

3. A magnet freely suspended arranges itself so that these poles point nearly north and south. This is called the *directive property*, or *polarity* of the magnet.

4. When two magnets approach each other, the poles of the *same names*, that is, both north or both south, repel each other.

5. Poles of different names attract each other.

6. The loadstone is an iron ore naturally possessing magnetism.

7. Magnetism may be communicated to iron and steel.

8. A steel needle rendered magnetic, and fitted up in a box, so as to move freely in any direction, constitutes the mariner's compass.

Charles. I think there is a similarity between electricity and magnetism.

Tutor. You are right ; there is a considerable analogy, and a remarkable difference also between magnetism and electricity.

ELECTRICITY is of two sorts, positive and negative ; bodies possessed of the same sort of electricity, repel each other, and those possessed of different sorts attract each other.—In **MAGNETISM**, every magnet has two poles ; poles of the same name repel each other, and the contrary poles attract each other.

In **ELECTRICITY**, when a body, in its natural state, is brought near to one that is electrified, it acquires a contrary electricity, and becomes attracted by it.—In **MAGNETISM**, when an iron substance is brought near one pole of a magnet, it acquires a contrary polarity, and becomes attracted by it.

One sort of electricity cannot be produced by itself. In like manner, no body can have only one magnetic pole.

The electric virtue may be retained by electrics, but it pervades conducting substances. The magnetic virtue is retained by iron, but it pervades all other bodies.

On the contrary : the magnetic power differs from the electric, as it does not affect senses

**The electric virtue resides on the su
electrified bodies, but the magnetic is i**

**A magnet loses nothing of its power
netizing bodies, but an electrified bo
part of its electricity by electrifying o
dies.**

ELECTRICITY.

VOL. III.—N

2000

CONVERSATION XXVII.

INTRODUCTION.

The early History of Electricity.

TUTOR. If I rub pretty briskly with my hand this stick of sealing-wax, and then hold it near any small light substances, as little pieces of paper, the wax will attract them; that is, if the wax be held within an inch or more of the paper, they will jump up, and adhere to it.

Charles. They do; and I think I have heard you call this the effects of electricity, but I do not know what electricity is.

Tutor. It is the case with this part of science as with many others, we know it only by the effects which it produces. As I have not hitherto, in these conversations, attempted to bewilder your minds with useless theories, neither will I, in the present case, attempt to say what the electrical fluid is: its action is well known; it seems diffused over every portion of matter

with which we are acquainted, and, by the use of proper methods, it is as easily collected from surrounding bodies as water is taken from a river.

James. I see no fluid attaching to the sealing-wax when you have rubbed it.

Tutor. You do not see the air which you breathe, and with which you are surrounded; yet we have shown you* that it is a fluid, and may be taken from any vessel, as certainly though not with so much ease, as water may be poured from this glass. With the exercise of a small degree of patience, you shall see such experiments as will not fail to convince you that there is as certainly a fluid, which is called the electric fluid, as there are such fluids as water and air.

Charles. Water must have been known since the creation, and the existence of the air could not long remain a secret, but who discovered the electric fluid, which is not at all evident to the sense either of sight or feeling?

Tutor. Thales, who lived six centuries before the Christian era, was the first who observed the electrical properties of amber, and he was so struck with the appearances, that he supposed it to be animated:

Bright *amber* shines on his electric throne,
And adds ethereal lustre to his own.

DARWIN.

* See Vol. II.

es. Does amber attract light bodies like
5-wax?

or. Yes, it does; and there are many
substances, as well as these, that have the
power. After Thales, the first person we
f that noticed this subject was Theophras-
who discovered that *tourmalin* has the
of attracting light bodies. It does not,
er, appear that the subject, though very
s, excited much attention till about 200
ago, when Dr. Gilbert, an English phy-
examined a great variety of substances,
view of ascertaining how far they might
ght not be ranked among *electrics*.

ries. What is meant by an *electric*?

or. Any substance being excited or rub-
the hand, or by a woollen cloth, or other
, and having the power of attracting light
, is called an *electric*.

es. Is not electricity accompanied with a
ar kind of light, and with sparks?

or. It is, of which we shall speak more
ge hereafter: the celebrated Mr. Boyle is
ied to have been one of the first persons
ot a glimpse of the electrical light, or
eems to have noticed it, by rubbing a
nd in the dark. But he little imagined,
t time, what astonishing effects would af-
ds be produced by the same power. Sir
Newton was the first who observed that

excited glass attracted light bodies on the opposite to that on which it was rubbed.

Charles. How did he make the discovery

Tutor. Having laid upon the table a piece of glass, about two inches broad, a brass ring, by which it was raised from the table about the eighth of an inch, and then rubbed the glass, some little bits of paper which were under it were attracted by it, and moved nimbly to and from the glass.

Charles. I remember standing by a glass when he was cementing, that is, rubbing some window-lights with oil, and cleaning it with a stiff brush and whiting, and the little pieces of whiting, under the glass, kept continually leaping up and down, as the brush moved over the glass.

Tutor. That was, undoubtedly, an electrical appearance, but I do not remember having ever seen it noticed by any writer on electricity. A complete history of this science is given by Dr. Priestley, which will, hereafter, afford you much entertainment and interesting instruction. To-morrow we shall enter into the practical part of the subject: and I doubt that the experiments in this part of science will be as interesting as those in any other which you have been studying. The electrical light, exhibited in different forms; the various signs of attraction and repulsion acting on

bodies ; the electric shock, and the explosion the battery, will give you pleasure, and excite your admiration.

CONVERSATION XXVIII.

Of Electric Attraction and Repulsion—Of Electrics and Conductors.

Tutor. You must for a little time, that till we exhibit before you experiments to prove it, take it for granted that the earth, and all bodies with which we are acquainted, contain a certain quantity of exceedingly elastic and penetrating fluid, which philosophers call the electric fluid.

Charles. You say a certain quantity : is it limited ?

Tutor. Like other bodies, it undoubtedly has its limits ; this glass will hold a certain quantity of water, but if I attempt to pour into it more than that quantity, a part will flow over. So it is with the electric fluid : there is a certain quantity which belongs to all bodies, and this is called their natural quantity, and so long

as a body contains neither more nor less than this quantity, no sensible effect is produced.

James. Has this table electricity in it?

Tutor. Yes, and so has the inkstand, and every thing else in the room; and if I were to take proper means to put more into it than it now has, and you were to put your knuckle to it, it would throw it out in the shape of sparks.

James. I should like to see this done.

Charles. But what would happen if you should take away some of its natural quantity?

Tutor. Why then, if you presented any part of your body to the table, as your knuckle, a spark would go from you to the table.

James. But, perhaps, Charles might not have more than his natural share, and in that case he could not spare any.

Tutor. True; but to provide for this, the earth on which he stands would lend him a little to make up for what he parted with to the table.

James. This must be an amusing study; I think I shall like it better than any of the others.

Tutor. Take care that you do not pay for the amusement before we have done.

Here is a glass tube about eighteen inches long, and perhaps an inch or more in diameter; I rub it up and down quickly in my hand, which is dry and warm, and now I will present it to these fragments of paper, thread, and gold-leaf:

we see they all move to it. That is called electrical attraction.

Charles. They jump back again now, and now they return to the glass.

Tutor. They are, in fact, alternately attracted and repelled, and this will last several minutes if the glass be strongly excited. I will rub it again; present your knuckle to it in several parts, one after another.

James. What is that snapping? I feel likewise something like the pricking of a pin.

Tutor. The snapping is occasioned by little sparks which come from the tube to your knuckle, and these give the sensation of pain.

Let us go into a dark room, and repeat the experiment.

Charles. The sparks are evident enough now, but I do not know where they can come from.

Tutor. The air, and every thing is full of the fluid which appears in the shape of sparks; and whatever be the cause, which I do not attempt to explain, the rubbing of the glass with the hand collects it from the air, and having now more than its natural share, it parts with it to you, or to me, or to any body else that may be near enough to receive it.

James. Will any other substance besides the hand, excite the tube?

Tutor. Yes, many others, and these, in this science, are called the *rubbers*; and the glass

tube, or whatever is capable of being thus excited, is called an *electric*.

Charles. Are not all sorts of solid substances capable of being excited?

Tutor. You may rub this poker, or the round ruler for ever, without obtaining an electric spark from them.

James. But you said one might get a spark from the mahogany table, if it had more than its share.

Tutor. So I say you may have sparks from the poker, or ruler, if they possess more than their common share of the electric fluid.

Charles. How do you distinguish between bodies that can be, and those that cannot be excited?

Tutor. The former, as I have told you, are called *electrics*, as the glass tube; the latter, such as the poker, the ruler, your body, and a thousand other substances, are denominated *conductors*.

Charles. I should be glad to know the reason of the distinction, because I shall be more likely to remember it.

Tutor. That is right: when you held your knuckle to the glass tube, you had several sparks from the different parts of it: but if by any means, overcharged a conductor, as the poker, all the electricity will come away at a single spark, because the superabundant quantity

ty flows instantaneously from every part to that point where it has an opportunity of getting away. I will illustrate this by an experiment. At first of all, let me tell you, that all *electrics* are called also *non-conductors*.

James. Do you call the glass tube a *non-conductor* because it does not suffer the electric fluid to pass from one part of it to another?

Tutor. I do:—silk, if dry, is a non-conductor. With this skein of sewing-silk, I hang the poker or other metal substance A (Plate VII. fig. 1.) to a hook in the ceiling, so as to be about twelve inches from it; underneath, and near the extremity, are some small substances, bits of paper, &c. I will excite the glass tube, and present it to the upper part of the poker.

Charles. They are all attracted, but now you take away the glass they are quiet.

Tutor. It is evident that the electric fluid passed from one part of the tube through the poker, which is a conductor, to the paper, and attracted it:—if the glass be properly excited, you may take sparks from the poker.

James. Would not the same happen if another glass tube were placed in the stead of the poker?

Tutor. You shall try.—Now I have put the glass in the place of the poker, but let me excite the other tube as much as I will, no effect can be

produced on the paper:—there are no signs of electrical attraction, which shows that the electric fluid will not pass through glass.

Charles. What would have happened if conducting substances had been used, instead of silk, to suspend the iron poker?

Tutor. If I had suspended the poker with a moistened hempen string, the electric fluid would have all passed away through that, and there would have been no (or very trifling) appearances of electricity at the end of the poker.

You may vary these experiments till you make yourselves perfect with regard to the distinction between electrics and conductors. Sealing-wax is an electric, and may be excited as well as a glass tube, and will produce similar effects. I will give you a list of *electrics*, and another of *conductors*, disposed according to the order of their perfection, beginning in each with the most perfect of their class: thus glass is a better *electric* than amber, and gold a better *conductor* than silver.

CONVERSATION XXIX.

Of the Electrical Machine.

Tutor. I will now explain to you the construction of the electrical machine, and shew you how to use it.

Charles. For what purpose is it used?

Tutor. Soon after the subject of the electric fluid engaged the attention of men of science they began to contrive the readiest methods of collecting large quantities of it. By rubbing this stick of sealing-wax, I can collect a small portion: if I excite or rub the glass tube, I collect still more. The object, therefore, was, to find out a machine by which the largest quantity could be collected, with as little trouble and expense as may be.

James. You get more electricity from the glass tube than from the sealing-wax, because the quantity is five or six times as large: by increasing the size of the tube, you would increase the quantity of the electric fluid, I should think.

Tutor. That is a natural conclusion. If you look to the table of electrics, which I shewed you yesterday, you will see that had the wax been as large as the glass tube, it would have collected so much of the electric fluid

, in its own nature, it is not so good an
ic.

urles. By the table, glass stands as the perfect electric, but there are several substances between it and wax, all of which are, I e, more perfect electrics than wax.

or. They are: Electricians, therefore, o hesitation as to the nature of the substance: they fixed on glass, which being easily l and run, or blown into all sorts of forms, that account, very valuable.

e most common form that is now used is f a glass cylinder, from five or six inches meter to ten or twelve. Here is one com- 7 fitted up (Plate VII. Fig. 2.) the cylinder is about eight inches in diameter, and or fourteen in length: this I turn round frame-work, with the handle D C.

es. What is the piece of black silk K for?

or. The cylinder would be of no use with- rubber, you know: on which account you e glass pillar R S, which, being cemented piece of hard wood, is made to screw in- bottom of the machine; on the pillar is ion, to which is attached a piece of black

urles. And I perceive the cushion is made ss very hard against the glass.

or. This pressure, when the cylinder is round fast, acts precisely like the rub-

rubber is fixed on a glass pillar, and glass does not conduct the electric fluid.

Charles. Nevertheless it does, by experiment, show some signs of attraction.

Tutor. Every body in nature with which we are acquainted possesses a portion of electricity, and therefore the signs which are now observed arise from the small quantity which exists on the rubber itself, and the atmosphere which immediately surrounds the machine.

Charles. Would the case be different if the rubber were fixed on a conducting substance instead of glass?

Tutor. It would; but there is a much better method: I will attach one end of the chain to the cushion at R, which being six feet long, lies on the table, or on the floor; and this you know is connected, by means of various objects, with the earth, which is the great reservoir of electricity.

James. It is indeed very powerful. What a crackling noise it makes!

Tutor. Shut the window-shutters.

Charles. The appearance is very beautiful: the flashes from the silk dart all round the cylinder.

Tutor. I will now bring to the cylinder the zinc conductor L, which is also placed on a glass pillar, F N, fixed in the stand at F.

James. What are the points in the tin conductor for?

Tutor. They are intended to collect the fluid from the cylinder. I will turn the cylinder, and do you hold your knuckle within four or five inches of the conductor.

Charles. The painful sensations which these sparks occasion, prove that the electric fluid is a very powerful agent, when collected in large quantities.

Tutor. To show you the nature of conducting bodies, I will now throw another brass chain over the conductor, so that one end of it may be on the floor. See now if you can get any sparks, while I turn the machine.

James. No, I can get none, put my knuckle near to it as I will.—Does it all run away by the chain?

Tutor. It does; a piece of brass or iron wire would do as well; and so would any conducting substance, which touched the conductor with one end, and the floor with the other: your body

ELECTRICITY.

would do as well as the chain. Place your hand on the conductor, while I turn round the cylinder: and let your brother bring his knuckle near the conductor.

Charles. I can get no spark.

Tutor. It runs through James to the earth, and you see his body is a conductor as well as the chain. With a very little contrivance, I can take sparks from you or James, as well as you did from the conductor.

James. I should like to see how that is done.

Tutor. Here is a small stool, having a mahogany top and glass legs. If you stand on the stool and put your hand on the conductor, the electricity will pass from the conductor to your body.

Charles. Will the glass legs prevent it from running from him to the earth?

Tutor. They will: and therefore what receives from the conductor, he will be ready to part with to any of the surrounding bodies to you, if you bring your hand near end any part of him.

James. The sparks are more painful when passing through my clothes, than when I put them on my bare hand.

Tutor. They are: you understand the process.

Charles. By means of the chain to the ground, the electric fluid is collected on the earth on the glass cylinder, which passes through the points to the conductor.

it may be conveyed away again by means of other conductors.

Tutor. Whatever body is supported, or prevented from touching the earth, or communicating with it, by means of glass or other non-conducting substances, is said to be *insulated*. Thus a body suspended on a silk line is insulated, and so is any substance that stands on glass, or resin, or wax, provided that these are in a dry state, for moisture will conduct away the electric fluid from any charged body.

CONVERSATION XXX.

Of the Electrical Machine.

Charles. What is that shining stuff which I saw you put to the rubber yesterday?

Tutor. It is called *amalgam*: the rubber, by itself, would produce but a slight excitation: its power, however, is greatly increased by laying upon it a little of this amalgam, which is made of quicksilver, zinc, and tinfoil, with a little tallow or mutton suet.

James. Is there any art required in using this amalgam?

Tutor. When the rubber and silk flap are very clean and dry, and in their place, then spread a little of the amalgam upon a piece of leather, and apply it to the upper part of the glass cylinder, while it is revolving from you; by this means, particles of the amalgam will be carried by the glass itself to the lower part of the rubber, and will increase the excitation.

Charles. I think I once saw a globe, instead of a cylinder, for an electrical machine.

Tutor. You might: globes were used before cylinders, but the latter are the most convenient of the two. The most powerful electrical machines are fitted with flat plates of glass. In our experiments, we shall be content with the cylinder, which will answer every purpose of explaining the principles of the science.

James. As I was able to conduct the electricity from the tin conductor to the ground, could I likewise act the part of the chain, by conducting the fluid from the earth to the cushion?

Tutor. Undoubtedly: I will take off the chain, and now do you keep your hand on the cushion, while I turn the handle.

James. I see the machine works as well as when the chain was on the ground.

Tutor. Keep your present position, but stand on the stool with glass legs; by which means there is now all communication cut off between

cushion and the earth ; in other words, the hion is completely insulated, and can only e from you what electricity it can get from ir body. Go, Charles, and shake hands with ir brother.

Charles. It does not appear that the machine d taken all the electricity from him, for he ve me a smart spark.

Tutor. You are mistaken ; he gave you no- ng, but he took a spark from you.

Charles. I stood on the ground ; I was not ctrified : how then could I give him a spark ?

Tutor. The machine had taken from James e electricity that was in his body, and by ading on the stool, that is, by being insured, he had no means of receiving any more m the earth, or any surrounding objects ; the ment, therefore, you brought your hand near n, the electricity passed from you to him.

Charles. I certainly felt the spark, but whether went out of, or entered into, my hand, I cant tell : have I then less than my share now ?

Tutor. No : what you gave to your brother is supplied immediately from the earth. Here another glass-legged stool ; do you stand on is, but at the distance of a foot or two from ur brother, who still keeps his place. I take e electricity from him by turning the machine, d as he stands on the stool, he has now less an his share. But you have your natural

share : because though you also a yet you are out of the influence of it extend, therefore, your hand, and part of the electric fluid that is in

Charles. I have given him a spa

Tutor. And being yourself in have now less than your natural supply which you shall have soon give me your hand. You draw it my touching it !

Charles. I did ; but it was near a strong spark from you.

Tutor. When a person has less than his natural share, he is said to be electrified *minus*, or negatively : but if more than his natural share, he is said to be electrified *plus*, or positively.

James. Then before Charles gave me a spark, I was electrified minus ; and when he had given it to me, he was electrified plus.

Tutor. That is right. Suppose you stand on a stool and hold the rubber, and Charles on another stool, and touch the prime conductor, while I turn the machine, which will be plus, and which minus electrifies the rubber.

James. I shall be minus, because I touch the rubber : and Charles will be plus, because he receives from the conductor what I give to the rubber, and which is carried by the machine to the conductor.

ctor. You then have less than your share, your brother has more than he ought to

Now if I get another glass-legged stool, take from Charles what he has too much, give it to you who have too little.

arles. Is it necessary that you should be ated for this purpose?

ctor. By being insulated I may perhaps back to James the very electricity which d from him to you. But if I stand on the id, the quantity which I take from you pass into the earth, because I cannot, un- am insulated, retain more than my natu- iare.

nes. And what is given by you to me is ise instantaneously supplied by the earth.

tor. It is. Let us make another experiment ow that the electric fluid is taken from the

. Here are some little balls (Plate VII. 3.) made of the pith of elder: they are n thread, and being very light, are well ed to our purpose.

ile the chain is on the cushion, and I work achine, do you bring the balls near the ictor by holding the thread at D.

nes. They are attracted by it, and now vo balls repel each other, as in the figure

tor. I ought to have told you, that the up- art D of the line is silk, by which means now the balls are insulated, as silk is a

non-*I take the chain off from the cushion, and put it on the conductor, so as to hang on the ground, while I turn the machine. Will the balls be affected now, if you hold them to the conductor?*

James. No, they are not?

Tutor. Take them to the cushion.

Charles. They are attracted and repelled by being brought near the cushion, as they were before, by being carried to the conductor.

Tutor. Yes, and you may now take them from the cushion as you did just now from the conductor: in both cases, it must be evident that the electric fluid is brought from the cushion.

Some machines are furnished with two conductors, one of which is connected with the cushion, the other such as we have described. Turn the cylinder, and both conductors will be electrified; but any body which is brought within the influence of these, will be attracted to one of the conductors, and repelled by the other, and if a chain or wire be made to connect the two together, neither will exhibit any electrical appearances: they seem, therefore, to be in opposite states; accordingly electricians say, that the conductor connected with the cushion is negatively electrified, and the other is positively electrified.

CONVERSATION XXXI.

—

Of Electrical Attraction and Repulsion.

nes. What is this large roll of sealing-wax

tor. As I mean to explain, this morning, principles of electrical attraction and repulsion, I have, besides the electrical machine, brought out for use a roll of sealing-wax, which is about fifteen inches long, and an inch and a half in diameter; and the long glass tube.

arles. Are they not both electrics, and capable of being excited?

tor. They are; but the electricity produced by exciting them has different or contrary properties.

nes. Are there two kinds of electrics then?

tor. We will show you an experiment before we attempt to give any theory.—I will excite the glass tube, and Charles shall excite the

Now do you bring the pith-balls, which are suspended on silk (Fig. 3.) to the tube.

are suddenly drawn to it, and now they are repelled from one another, and likewise from the tube, for you cannot easily make them adhere to it again:—but take them to the excited

James. The wax attracts the fully : now they fall together again in the same state as they were were brought to the excited tube

Tutor. Repeat the experiment again, because on this two different have been formed. One of which are two electricities, called by philosophers the *vitreous* or positive and *resinous* or negative electricity.

Charles. Why are they called *resinous*?

Tutor. The word *vitreous* signifies any *glassy* substance ; and *nous* is used to denote that the produced by resins, wax, &c. possess qualities from that produced by

James. Is it not natural to suppose are two electricities, since the one attracts the very same bodies that the other repels ?

Tutor. It may be as easily explained supposing that every body, in its nature possesses a certain quantity of them, and if a part of it be taken away, it will endeavour to get it from other bodies ; or if there is more upon it than its natural quantity, it will endeavour to communicate readily to other bodies that come in contact with it.

Charles. I do not understand this.

Tutor. If I excite this glass tube

which it exhibits is supposed to come from hand ; but if I excite the roll of wax in the same way, the effect is, according to this theory, that a part of the electric fluid naturally clinging to the wax, passes from it through hand to the earth : and the wax being surrounded by the air, which, in its dry state, is a conductor, remains exhausted, and is ready to take sparks from any body that may be presented to it.

Ques. Can you distinguish that the sparks pass from the glass to the hand ; and, on the contrary, from the hand to the wax ?

Autor. No : the velocity with which the electric spark moves, renders it impossible to say what course it takes ; but I shall show you other arguments which seem to justify this theory : as Nature always works by the simplest means, it seems more consistent with her usual operations, that there should be one fluid rather than two, provided that known facts can be equally well accounted for, by one as by two.

Charles. Can you account for all the leading facts by either theory ?

Autor. Yes, we can.

You saw when the pith-balls were electrified, repelled one another. It is a general principle in electricity that two bodies having more than their natural share of the electric fluid, repel one another. But if one have more,

and the other less, than its share, they will attract one another.

James. How is this shown?

Tutor. I will hold this ball, which is insulated, by a silk thread, to the conductor, and do you, Charles, do the same with the other. Let us now bring them together.

Charles. No, we cannot: they fly from one another.

Tutor. I will hold mine to the insulated cushion, and you shall hold yours to the conductor while the machine is turned; now I suspect they will attract one another.

James. They do indeed.

Charles. The reason is this; that the cushion and whatever is in contact with it, parts with a portion of its electricity; but the conductor and the adjoining bodies, have more than their share; therefore, the ball applied to the cushion, being negatively electrified, will attract the one connected with the conductor, which is positively electrified.

Tutor. Here is a tuft of feathers, which I stick in a small hole in the conductor: now see what happens when I turn the cylinder.

James. They all endeavour to avoid each other, and stand erect, in a beautiful manner. Let me take a spark from the conductor: now they fall down in a moment.

Tutor. When I turned the wheel they all had more than their share of the electric fluid, and

heretofore they repelled one another, but the moment the electricity was taken away, they fell into their natural position. A large plume of feathers, when electrified, grows beautifully rigid, expanding its fibres in all directions, and they collapse when the electricity is taken off.

James. Could you make the hairs on my head repel one another?

Tutor. Yes, that I can. Stand on the glass-legged stool, and hold the chain that hangs on the conductor, in your hand, while I turn the machine.

Charles. Now your hairs stand all an end.

James. And I feel something like cobwebs over my face.

Tutor. There are, however, no cobwebs, but that is the sensation which a person always experiences if he be highly electrified. Hold the lith-ball, Charles, near your brother's face.

James. It is attracted in the same manner as was before with the conductor.

Tutor. Hence you may lay it down as a general rule, that all light substances coming within the influence of an electrified body, are attracted by it whether it is electrified positively or negatively.

Charles. Because they are attracted by the positive electricity to receive some of the superabundant quantity; and by the negative, to give away some that they possess.

Tutor. Just so : and when they have received as much as they can contain, they are repelled by the electrified body. The same thing may be shown in various ways. Having excited this glass tube, either by drawing it several times through my hand, or by means of a piece of flannel, I will bring it near this small feather. See how quickly it jumps to the glass.

James. It does, and sticks to it.

Tutor. You will observe, that after a minute or two, it will have taken as much electricity from the tube as it can hold, when it will suddenly be repelled, and jump to the nearest conductor ; upon which it will discharge the superabundant electricity that it has acquired.

James. I see it is now going to the ground, that being the nearest conductor.

Tutor. I will prevent it by holding the electrified tube between it and the floor. You see how unwilling it is to come again in contact with the tube : by pursuing, I can drive it where I please without touching it.

Charles. That is, because the glass and the feather are both loaded with the same electricity.

Tutor. Let the feather touch the ground, or any other conductor, and you will see that it will jump to the tube as fast as it did before.

I will suspend this brass plate, which is about five inches in diameter, to the conductor, and at the distance of three or four inches below I will place some small feathers, or bits of paper

to the figures of men and women. They lie quiet at present; observe their motions as as I turn the wheel.

mes. They exhibit a pretty country dance; jump up to the top plate, and then down

l.
stor. The same principle is evident in all experiments. The upper plate has more its own share of the electric fluid, which acts the little figures: as soon as they have ved a portion of it, they go down to give it e lower plate; and so it will continue till pper plate is discharged of its superabun- quantity.

will take away the plates, and hang a chain e conductor, the end of which shall lie in al folds in a glass tumbler; if I turn the ine, the electric fluid will run through the 1, and will electrify the inside of the glass.

done, I turn it quickly over eight or ten l pith-balls, which lie on the table.

arles. That is a very amusing sight; how jump about! They serve also to fetch the ricity from the glass, and carry it to the

l.
utor. If, instead of the lower metal plate, ld in my hand a pane of dry and very clean s, by the corner, the paper figures or pith-; will not move, because glass being a non- lucting substance, it has no power of carry- away the superabundant electricity from the

plate suspended from the conductor. But hold the glass flat in my hand, the figure be attracted and repelled, which shows the electric fluid will pass through thin glass.

Take now the following results, and commit them to your memory.

(1.) If two insulated pith-balls, be brought near the conductor, they will repel each other.

(2.) If an insulated conductor be connected with the cushion, and two insulated pith-balls be electrified by it, they will repel each other.

(3.) If one insulated ball be electrified by the prime conductor, and another by the conductor connected with the cushion, they will attract each other.

(4.) If one ball be electrified by glass and another by wax, they will attract each other.

(5.) If one ball be electrified by a smooth glass tube, and another by a rough excited glass tube, they will attract one another.

CONVERSATION XXXII.

Of Electrical Attraction and Repulsion.

Tutor. I will show you another instance of the effects of electrical attraction and repulsion.

This apparatus (Plate VII. Fig. 4.) consists of three bells suspended from a brass-wire, the two outer ones by small brass chains ; the middle bell, and the two clappers $x x$, are suspended on silk. From the middle bell there is a chain n , which goes to the table, or any other conducting substance. The bells are now to be hung by c on the conductor, and the electrical machine to be put in motion.

James. The clappers go from bell to bell, and make very pretty music : how do you explain this ?

Tutor. The electric fluid runs down the chains a and b to the bells $A B$, these having more than their natural quantity, attract the clappers $x x$ which take a portion from A and B , and carry it to the centre bell n , and this, by means of the chain, conveys it to the earth.

Charles. Would not the same effect be produced if the clappers were not suspended on silk ?

Tutor. Certainly not : nor will it be produced if the chain be taken away from the bell n , because then there is no way left to carry off the electric fluid to the earth.

Another amusing experiment is thus shown. Let there be two wires placed exactly one above another, and parallel ; the upper one must be suspended from the conductor, the other is to communicate with the table. A light imag

placed between these will, when the conductor is electrified, appear like a rope-dancer.

This piece of leaf brass is called the *electric fish*; one end is a sort of obtuse angle, the other is acute: if the large end be presented toward an electrified conductor, it will fix to it, and from its wavering motion, it will appear to be animated.

This property of attraction and repulsion has led to many inventions of instruments called *electrometers*.

James. Is not an electrometer a machine to measure the strength of the electricity?

Tutor. Yes; and this is one of the most simple, (Plate VII. Fig. 5.) and it depends entirely upon the repulsion which takes place between two bodies in a state of electrification. It consists of a light rod and a pith-ball, hanging parallel to the stem, but turning on the centre of a semicircle, so as to keep close to its graduated limb. This is to be placed in a hole at the conductor *L*, and according as the conductor is more or less electrified, the ball will fly farther from the stem.

Charles. If the circular part be marked with degrees, you may ascertain, I suppose, pretty accurately, the strength of any given charge.

Tutor. Yes, you may; but you see how fast the air carries away the electricity, it scarcely remains a single moment in the place to which

it was repelled. Two pith-balls may be suspended parallel to one another, on silken threads, and applied to any part of an electrical machine, and they will, by their repulsion, serve for an electrometer, for they will repel one another the more, as the machine acts more powerfully.

James. Has this any advantage over the other?

Tutor. It serves to show whether the electricity be negative or positive; for if it be positive, by applying an excited stick of sealing-wax, the threads will fall together again; but if it be negative, excited sealing-wax, or resin, or sulphur, or even a rod of glass, the polish of which is taken off, will make them recede farther.

We have now perhaps said enough respecting electrical attraction and repulsion, at least for the present; I wish you, however, to commit the following results to your memory.

- (1.) Bodies that are electrified *positively* repel each other.
- (2.) Bodies that are electrified *negatively* repel each other.

Charles. Do you mean, that if two bodies have either more or less of the electric fluid than their natural share, they will repel each other if brought sufficiently near?

Tutor. That is exactly what I mean.

- (3.) Bodies electrified by contrary powers;

that is, two bodies, one having more, and the other less, than its natural share, attract each other very strongly.

(4.) Bodies that are electrified attract light substances which are not electrified.

These are facts which, I trust, have been made evident to your senses. To-morrow we will describe what is usually called the Leyden phial.

CONVERSATION XXXIII.

Of the Leyden Phial or Jar.

Tutor. I will take away the wires and the ball from the conductor, and then remove the conductor an inch or two farther from the cylinder. If the machine acts strongly, bring an insulated pith-ball, that is, you know, one hanging on silk, to the end of the conductor, nearest to the glass cylinder.

Charles. It is immediately attracted.

Tutor. Carry it to the other end of the conductor, and see what happens.

Charles. It is attracted again; but I thought it would have been repelled.

Tutor. Then as the ball was electrified before, and is still *attracted*, you are sure that the electricity of the two ends of the conductor are different names; that is, one is *plus*, and the other *minus*.

James. Which is the positive, and which is the negative end?

Tutor. The end of the conductor which is nearest to the cylinder, becomes possessed of electricity different from that of the cylinder itself.

James. Do you mean that if the cylinder is positively electrified, the end of the conductor next to it is electrified negatively?

Tutor. I do: and this you may see by holding an insulated pith-ball between them.

Charles. Yes, it is now very evident, for the ball fetches and carries as we have seen it before.

Tutor. What you have seen with regard to the conductor, is equally true with respect to non-conducting bodies. Here is a common glass tumbler: if I throw within-side it a greater portion of electricity than its natural share, and hold it in my hand, or place it on any conducting substance, as a table, a part of the electric fluid, that naturally belongs to the outside, will make its escape through my body, on to the table.

Charles. Let me try this.

VOL. III.—Q

Tutor. But you must be careful that not break the glass.

Charles. I will hang the chain on the ductor, and let the other end lie on the top of the glass, and James will turn the machine.

Tutor. You must take care that the chain does not touch the edge of the glass, then the electric fluid will, by that means, pass from one side of it to the other, and you may experiment.

James. If I have turned the machine, you may take the chain out, and try the two sides of the insulated pith-ball.

Charles. What is this? Something has passed through my arms and shoulders.

Tutor. That is a trifling electric shock you might have avoided, if you had waited for my directions.

Charles. Indeed it was not trifling: I feel it now.

Tutor. This leads us to the Leyden jar, so called, because the discovery was first made at Leyden, in Holland, and by means of a glass jar or small bottle.

James. Was it found out in the same manner as Charles has just discovered it?

Tutor. Nearly so. Mr. Cuneus, a Dutch philosopher, was holding a glass phial in his hand about half filled with water, but the sides of the phial were dry, the water, and the outside was quite dry,

also hung from the conductor of an electrical machine into the water.

James. Did that answer to the chain?

Tutor. Just so: and, like Charles, he was going to disengage the wire with one hand, as he held the bottle in the other, and was surprised and alarmed by a sudden shock in his arms, and through his breast, which he had not the least expected.

Charles. I do not think there was any thing to be alarmed at.

Tutor. The shock which he felt was, probably, something severer than that which you have just experienced: but the terror was evidently increased by its coming so completely unexpected.

When M. Muschenbroeck first felt the shock, which was by means of a thin glass bowl, and very slight, he wrote to M. Reaumur, that he felt himself struck in his arms, shoulders, and breast, so that he lost his breath, and was two whole days before he recovered from the effects of the blow.

Charles. Perhaps he meant the fright.

Tutor. Terror seems to have been the effect of the shock: for he adds, "I would not take a second shock, for the whole kingdom of France."

Mr. Ninkler, an experimental philosopher, at Leipsic, describes the shock as having given him convulsions, a heaviness in his head, such

Nevertheless, in the course of a few
received another shock, which caused

t, at the same time, driving away an quantity from the outside, the inside is ely electrified, and the outside is nega-electrified. To restore the equilibrium, t make a communication between the and inside with some conducting sub- . That is, I must make the same sub- touch, at the same time, the outside tin and that which is within, or, which is the hing, another substance that does touch it. rles. The brass wire touches the inside: herefore, with one hand touch the knob, ith the other the outside covering, will it icient?

or. It will: but I had rather you would ecause the shock will be more powerful should wish either myself or you to ex- ce. Here is a brass wire with two little r knobs *b* s screwed to it (Plate VII. Fig. will bring one of them, as *s*, to the outside, e other, *b*, to the ball *v* on the wire. es. What a brilliant spark, and what a noise!

or. The electric fluid, that occasions the and the noise, ran from the inside of the ough the wire to *s*, and spread itself over tside.

rles. Would it have gone through my f I had put one hand to the outside, and d the wire communicating with the in- with the other?

Tutor. It would, and you may see that the shock would have been in proportion to the quantity of the fluid collected. The one I used may be called a discharge jar; here is a more convenient one (Fig. 8.): the handle is solid glass, and is in a brass socket, and the brass work is as Fig. 7, only by turning on a screw the jar may be opened to any extent.

James. Why is the handle glass?

Tutor. Because glass being a non-conductor the electric fluid passes through without affecting the hand; whereas, if it were metal, a small sensation was perceived when discharged the jar.

Charles. Would the jar never become discharged itself?

Tutor. Yes: by exposure to time, the charge of the jar will gradually dissipate, for the electric fluid of the inside will escape to the outside of the jar. Philosophers make it a rule never to use a jar in its charged state.

CONVERSATION XXXIV.

Of the Leyden Jar—Lane's Discharging Electrometer, and the Electrical Battery.

Charles. In discharging the jar yesterday, I observed that when one of the discharging-rods touched the outside of the jar, the flash and report took place before the other end came in contact with the brass wire that communicates with the inside coating.

Tutor. Yes, it acts in the same manner as when you take a spark from the conductor; you do not, for that purpose, bring your knuckle close to the tin.

James. Sometimes, when the machine acts very powerfully, you may get the spark at the distance of several inches.

Tutor. By the same principle, the higher an electrical or Leyden jar is charged, the more easily, or at a greater distance, is it discharged.

Charles. From your experiments it does not seem that it will discharge at so great a distance as that in which a spark may be taken from the conductor.

Tutor. Very frequently a jar will discharge itself, after it has accumulated as much of the electrical fluid as it can contain; that is, the

fluid which is thrown on the inside coating will make its way over the glass, though a non-conductor, on to the outside coating.

James. In a Leyden jar, after the first charge, you always, I perceive, take another and smaller one.

Tutor. The tin foil on the jar not being perfect conductor, the whole quantity of it will not pass at first from the inside to the outside; what remains is called the *residuum*, and if in a large jar, would give you a considerable shock; therefore, I advise you always, in charging an electrical jar, to take away the residuum before you venture to remove the apparatus. I will now describe an electrometer which depends, for its action, on the principle we have been describing.

Charles. Do you mean upon the jars charging before the outside and inside coatings are actually brought into contact?

Tutor. I do. (Plate VII. Fig. 10.) The arm *D* is made of glass, and proceeds from a socket on the wire of the electrical jar *F*. To the end of the glass arm is cemented another bracket *E*, through which a wire, with balls *a* and *c* at each end, will slide backwards and forwards.

James. So that it may be brought to a distance from the ball *A*, which is on the wire connected with the inside of the jar.

Tutor. Just so. When the jar *F* is set either

in contact, or very near the conductor, as is represented in the figure, and the ball *B* is set at the distance of the eighth of an inch from the ball *A*, let a wire *C K* be fixed between the ball *A* and the outside coating of the jar. Then as soon as the machine is worked, the jar cannot be charged beyond a certain point, for when the charge is strong enough to pass from *A* to the ball *B*, the discharge will take place, and the electric fluid collected in the inside will pass through the wire *C K* to the outside coating.

Charles. If you remove the balls to a greater distance from one another, will a stronger charge be required before the fluid can pass from the inside of the jar to the ball *B*, of the electrometer?

Tutor. Certainly: and therefore the discharge will be much stronger. This machine is called *Lane's Discharging Electrometer*, from the name of the person who invented it. It is very useful in applying the electric shock to medical purposes, as we shall see hereafter.

This box contains nine jars or *Leyden phials*; (Plate VIII. Fig. 9.) the wires which proceed from the inside of each three of these jars, are screwed or fastened to a common horizontal wire *E*, which is knobbed at each extremity, and by means of the wires *F F*, the inside coatings of 3 or 6, or the whole 9, may be connected.

sides of the box for?

Tutor. To this hook is fastened a wire, which communicates with the inside of the box, and, of course, with the outside of the jars. And, as you see, to this a wire is also fastened, which connects one branch of the discharging-rod.

James. Is there any particular art to in charging a battery?

Tutor. No: the best way is, to bring a rod or piece of wire, from the conductor to the balls on the rods that rest upon the jars, and then set the machine to work. The electric fluid passes from the conductor to the balls of all the jars, till it is charged sufficiently for the purpose. Great caution, however, must be used when you come to make exper-

presented in the plate, which is one of the smallest made; a shock may be given, which, if passed through the head, or other vital parts of the body, may be attended with very mischievous effects.

James. How do you know when the battery is properly charged?

Tutor. The quadrant electrometer (Plate VII. Fig. 5.) is the best guide, and this may be fixed either on the conductor, or upon one of the rods of the battery. But if it is fixed on the battery, the stem of it should be of a good length, not less than twelve or fifteen inches.

Charles. How high will the index stand, when the battery is charged?

Tutor. It will seldom rise so high as 90° , because a machine, under the most favourable circumstances, cannot charge a battery so high, in proportion, as a single jar. You may reckon that a battery is well charged when the index rises as high as 60° , or between that and 70° .

James. Is there no danger of breaking the jars when the battery is very highly charged?

Tutor. Yes, there is; and if one jar be cracked, it is impossible to charge the others till the broken one be removed. To prevent accidents, it is recommended, not to discharge a battery through a good conductor, except the circuit is at least five feet long.

Charles. Do you mean the wire should be so long?

Tutor. Yes, if you pass the charge that; but you may carry it through a conductor.

Before a battery be used, the uncoated of the jars must be made perfectly clean and dry; the smallest particles of dust will carry away the electric fluid. And after an experiment always connect the wire from the lower ball, to prevent any residuum from remaining.

CONVERSATION XXXV.

Experiments made with the Electrical Battery.

Tutor. I will now show you some experiments with this large battery. To perform in perfect safety, I must beg you to stand at a good distance from it: this will prevent accidents.

Example 1. I take this quire of paper, and place it against the hook that comes out of the box; and when the battery is charged, I put one ball of the disc on the rod to a knob of one of the wires F, a

other knob to that part of the paper that lies against the wire, proceeding from the

You see what a hole it has made through every sheet of the paper. Smell the paper where the perforation is.

Charles. It smells like sulphur.

Tutor. Or more like phosphorus. You observe, in this experiment, that the electric fluid passed on the inside of the jars through the conducting-rod and paper, to the outside.

James. Why did it not pass through the paper in the same manner as it passed the brass discharging-rod, in which it made no hole?

Tutor. Paper is a non-conducting substance, but brass is a conductor: through the latter it passes without any resistance, and in its endeavor to get to the inside of the box, it burst the paper as you see. The same thing would have happened, had there been twice or thrice as much paper. The electric fluid of a single jar pierces through many sheets of paper.

Charles. Would it serve any other non-conducting substance in the same manner?

Tutor. Yes, it will even break a thin piece of glass, or of resin, or of sealing-wax, if they be exposed between the discharging rod and the inside of the coating of the battery.

Example 2. Place a piece of loaf-sugar in the position in which the quire of paper was just used, the sugar will be broken, and in the dark

VOL. III.—R

it will appear beautifully illuminated, and remain so for many seconds of time.

Example 3. Let the small piece of wire, proceeding from the hole in the box, be laid on one side of a plate, containing some spirits of wine, and, on the opposite side of the plate, bring one of the knobs of the discharging-rod, while the other is carried to the wires connected with the inside of the jars.

Charles. Then the electric fluid will have a passage through the spirit.

Tutor. It will set it on fire instantly.

Example 4. Take two slips of common window-glass, about four inches long, and one inch broad: put a slip of gold-leaf between the glasses, leaving a small part of it out at each end, then tie the glasses together, or press them with a heavy weight, and send the charge of the battery through it, by connecting one end of the glass with the outside of the jars, and bringing the discharging-rod to the other end, and to the wires of the inside of the battery.

James. Will it break the glass?

Tutor. It probably will: but whether it does or not, the gold-leaf will be forced into the pores of the glass, so as to appear like glass stained with gold, which nothing can wash away.

Example 5. If the gold-leaf be put between two cards, and a strong charge passed through

it, it will be completely fused or melted, the mark of which will appear on the card.

This instrument, (Plate VII. Fig. 11.) called a universal discharger, is very useful for passing charges through many substances. B B are glass pillars cemented into the frame A. To each of the pillars is cemented a brass cap, and a double joint for horizontal and vertical motions; on the top of each joint is a spring tube, which holds the sliding wires c x, c x, so that they may be set at various distances from each other, and turned in any direction; the extremities of the wires are pointed, but with screws, at about half an inch from the points, to receive balls. The table E D, inlaid with a piece of ivory, is made to move up and down in a socket, and a screw fastens it to any required height. The rings c c are very convenient for fixing a chain or wire to them, which proceeds from the conductor.

Charles. Do you lay any thing on the ivory, between the balls, when you want to send the charge of a battery through it?

Tutor. Yes; and by drawing out the wires, the balls may be separated to any distance less than the length of the ivory. The figure H (Plate VII. Fig. 12.) represents a press, which may be substituted in the place of the table E D. It consists of two flat pieces of mahogany, which may be brought together by screws.

James. Then instead of tying the slips of

glass together, in Example 4, you might have done it better by making use of the press.

Tutor. I might; but I was willing to show you how the thing might be done, if no such apparatus as this were at hand. The use of the table and press, which, in fact, always go together, is for keeping steady all descriptions of bodies through which the charge of a single jar, or any number of which a battery consists, is to be conveyed. We will now proceed with the experiments.

Example 6. I will take the knobs from the wires of the universal discharger, and having laid a piece of very dry writing paper on the table *E*, I place the points of the wires at an inch or more from one another; then, by connecting one of the rings *c* with the outside wire or hook of the battery, and bringing the discharging-rod from the other ring *c* to one of the knobs of the battery, you will see that the paper will be torn to pieces.

Example 7. The experiment which I am now going to make, you must never attempt by yourselves: I put a little gunpowder in the tube of a quill, open at both ends, and insert the pointed extremities of the two wires in it, so as to be within a quarter of an inch or less from each other. I now send the charge of the battery through it, and the gunpowder, you see, is instantly inflamed.

Example 8. Here is a very slender wire, no

a hundredth part of an inch in diameter, which I connect with the wires of the discharger, and send the charge of a battery through it, which will completely melt it, and you now perceive the little globules of iron instead of the thin wire.

Charles. Will other wires besides iron be melted in the same manner?

Tutor. Yes, if the battery be large enough, and the wires sufficiently thin, the experiment will succeed with them all: even with a single jar, if it be pretty large, very slender wire may be fused. But the charges of batteries have been used to determine the different conducting powers of the several metals.

James. If the charge is not strong enough to melt the wire, will it make it red hot?

Tutor. It will: and when the experiment is properly done, the course of the fluid may be discerned by its effects: for if the wire is about three inches long, it will be seen that the end of it, which is connected with the inside of the battery, is red hot first, and the redness proceeds towards the other.

Charles. That is a clear proof that the superabundant electricity accumulated in the inside is carried to the outside of the jars.

Tutor. Example 9. We have, in the present volume, discussed the subject of magnetism: and we may here observe, that by discharging the battery through a small sewing needle, it

will become magnetic, that is, if the needle be accurately suspended on a small piece of cork, in a basin of water, one end will, of itself, point to the north, and the other to the south.

Example 10. I will lay this chain on a sheet of writing paper, and send the charge of the battery through the chain; and you will see black marks will be left on the paper, in those places where the rings of the chain touch each other.

Example 11. Place a small piece of very dry wood between the balls of the universal dischargers, so that the fibres of the wood may be in the direction of the wires, and pass the charge of the battery through them, the wood will be torn in pieces. The points of the wires being run into the wood, and the shock passed through them, will effect the same thing.

Example 12. Here is a glass tube, open at both ends, six inches long, and a quarter of an inch in diameter. These pieces of cork, with wires in them, exactly fit the ends of the tube. I put in one cork, and fill the tube with water, then put the other cork in, and push the wires so that they nearly touch, and pass the charge of the battery through them, you see the tube is broken, and the water dispersed in every direction*.

* To prevent accidents, a wire cage, such as is used in some experiments on the air-pump, should be put over the tube before the discharge is made. Young persons should not attempt this experiment by themselves.

Charles. If water is a good conductor, how is it that the charge did not run through it without breaking the tube?

Tutor. The electric fluid, like common fire, converts the water into a highly elastic vapour, which occupying very suddenly a much larger space than the water, bursts the tube before it can effect any means of escape.

CONVERSATION XXXVI.

Of the Electric Spark, and Miscellaneous Experiments.

Tutor. I wish you to observe some facts connected with the electric spark. By means of the wire inserted in this ball, I fix it to the end of the conductor, and bring either another brass ball, or my knuckle to it, and if the machine act pretty powerfully, a long, crooked, brilliant spark will pass between the two balls, or between the knuckle and ball. If the conductor is negative, it receives the spark from the body; but if it is positive, the ball or the knuckle receives the spark from the conductor.

Charles. Does the size of the spark depend at all on the size of the conductor?

Tutor. The longest and largest sparks are obtained from a large conductor, provided the machine act very powerfully. When the quantity of electricity is small, the spark is straight; but when it is strong, and capable of striking at a greater distance, it assumes what is called a zig-zag direction.

James. If the electric fluid is fire, why does not the spark, which excites a painful sensation, burn me, when I receive it on my hand?

Tutor. **Ex. 1.** I have shown you that the charge from a battery will make iron wire red hot, and inflame gunpowder. Now stand on the stool with glass legs, and hold the chain from the conductor with one hand. Do you, Charles, hold this spoon, which contains some spirit of wine, to your brother, while I turn the machine, and a spark taken from his knuckle, if large, will set fire to the spirit.

Charles. It has indeed. Did you do nothing with the spirit?

Tutor. I only made the silver spoon pretty warm before I put the spirit into it.

Ex. 2. If a ball of box-wood be placed on the conductor instead of the brass ball, a spark taken from it will be of a fine red colour.

Ex. 3. An ivory ball placed on the conductor will be rendered very beautiful and luminous, if a strong spark be taken through its centre.

Ex. 4. Sparks taken over a piece of silver

leather appear of a green colour, and over gilt leather of a red colour.

Ex. 5. Here is a glass tube (Plate VII. Fig. 13.) round which, at small distances from each other, pieces of tin foil are pasted in a spiral form, from end to end: this tube is inclosed in a larger one, fitted with brass cups at each end, which are connected with the tin foil of the inner tube.—I hold one end *A* in my hand, and while one of you turns the machine, I will present the other end *B* to the conductor, to take sparks from it.—But first shut the window-shutters.

Charles. This is a very beautiful experiment.

Tutor. The beauty of it consists in the distance which is left between the pieces of tin foil, and by increasing the number of these distances, the brilliancy is very much heightened.

Ex. 6. The following is another experiment of the same kind. Here is a word, with which you are acquainted (Plate VIII. Fig. 14.) made on glass, by means of tin foil pasted on glass, fixed in a frame of baked wood. I hold the frame in my hand at *H*, and present the ball *G* to the conductor, and at every considerable spark, the word is beautifully illuminated.

Ex. 7. A piece of sponge, filled with water, and hung to a conductor, when electrified in a dark room, exhibits a beautiful appearance.

Ex. 8. This bottle is charged: if I bring the brass knob that stands out of it, to a basin of

ater which is insulated, it will attract a drop and on the removal of the bottle, it will assume a conical shape, and if brought near any conducting substance, it will fly to it in luminous streams.

Ex. 9. Place a drop of water on the conductor, and work the machine, the drop will assume a long spark, assume a conical figure, and carry some of the water with it.

Ex. 10. On this wire I have fixed a piece of sealing-wax, and having fixed the wire into the end of the conductor, I will light the wax, at the moment the machine is worked, the wax will fly off in the finest filaments imaginable.

Ex. 11. I will wrap some cotton-wool round one of the knobs of my discharging-rod, and fix the wool with finely bruised resin: I now discharge a Leyden jar, or a battery, in the common way, and the wool is instantly in a blaze. The covered knob must touch the knob of the jar, and the discharge should be effected as quickly as possible.

You will remember that the electric fluid always chooses the nearest road, and the conductors to travel by; in proof of which the following experiment:—

Ex. 12. With this chain I make a sort of (Plate VII. Fig. 15.) the wire *w* touches the outside of a charged jar, and the wire is brought to the knob of the jar, and in this position a brilliant spark is visible. But if the wire

to m , the electric fluid takes a shorter ; and, of course, only half of the w is in that part marked $m \approx y$: but if, in the wire w m , a dry stick be laid in, the electric matter will prefer a long- it, rather than go through a bad conduct- the whole w will be illuminated.

13. Here is a two ounce phial, half full of oil ; through the cork is passed a piece of wire, the end of which, within the phial is so bent as to touch the glass just below the surface of the oil. I place my thumb opposite the point of the wire in the bottle, and in this position take a spark from the charged conductor. You observe that the spark, to get to my thumb, has actually perforated the glass. In the same way, I can make holes all round the phial.

Charles. Would the experiment succeed with water, instead of oil ?

Tutor. No, it would not.

James. At any rate, we see the course of the electric fluid in this experiment, for the spark goes from the conductor down the wire, and through the glass to the thumb.

Tutor. Its direction is, however, better shown by this way.

Ex. 14. At that end of the conductor which is farthest from the machine, I fix a brass wire at six inches long, having a small brass ball

on its extremity. To this ball, when the machine is at work, I hold the flame of a wax taper.

Charles. The flame is evidently blown from the ball, in the direction of the electric fluid: it has a similar effect to the blast of a pair of bellows.

Ex. 15. I will fix a pointed wire upon the prime conductor, with the point outward, and another like wire upon the insulated rubber. Shut the window-shutter, and I will work the machine: now observe the points of the two wires.

James. They both are illuminated, but differently. The point on the conductor sends out a sort of brush of fire, but that on the rubber is illuminated with a star.

Tutor. You see then the difference between the positive and negative electricity.

CONVERSATION XXXVII.

Miscellaneous Experiments—Of the Electrophorus—Of the Electrometer, and the Thunder House.

Tutor. I shall proceed this morning with some other experiments on the electrical machine.

Ex. 1. Here are two wires, one of which is connected with the outside of this charged Leylen jar, the other is so bent as easily to touch the knob of the jar. The two straight ends I bring within the distance of the tenth of an inch of one another, and press them down with my thumb, and in this position, having darkened the room, I discharge the jar. Do you look upon my thumb.

Charles. It was so transparent that I think I even saw the bone of the thumb.—But did it not hurt you very much?

Tutor. With attention, you might observe the principal blood vessels, I believe; and the only inconvenience that I felt was a sort of tremour in my thumb, which is by no means painful. Had the wires been at double the distance, the shock would have probably made my thumb the circuit, which must have caused a more powerful and unpleasant sensation, but being so close, the electric fluid leaped from one wire to the other, and during this passage it illuminated my thumb, but did not go through it.

Ex. 2. If, instead of my thumb, a decanter full of water, having a flat bottom, were placed on the wires, and the discharge made, the whole of the water will be beautifully illuminated.

Ex. 3. This small pewter bucket is full of water, and I suspend it from the prime conductor, and put in a glass siphon, with a bore so narrow, that the water will hardly drop out.

See what will happen when I work the machine, but first make the room dark.

James. It runs now in a full stream, and in several streams, all of which are illuminated.

Tutor. Ex. 4. If the knob *a* (Plate vi. 16.) communicate with the outside of a Leyden jar, and the knob *b* with the inner coating, and each be held about two inches from a lighted candle *x*, and opposite to one the flame will spread towards each, and a charge will be made through it: this shews the conducting power of flame.

This instrument (Plate VIII. Fig. 17) consists of two circular plates, of which the largest *B* is about fifteen inches in diameter and the other *A* fourteen inches, is called an *electrophorus*. The under plate *B* is of glass, or sealing-wax, or of any other non-conducting substance: I have made one of a mixture of pitch and chalk boiled together. The upper plate *A* is sometimes made of wood and sometimes of tin plate, but this is covered very neatly with tin foil: *x* is a handle fixed to a socket, by which the upper plate is removed from the under one.

Charles. What do you mean by an *electrophorus*?

Tutor. It is, in fact, a sort of simple electrical machine, and is thus used. Rub the under plate *B* with a fine piece of new flannel, rabbit's, or hare's, or cat's skin, and with

EXPERIMENTS.

excited, place upon it the upper plate A, put your finger on the upper plate: then touch this plate by the glass handle *x*, and if you apply your knuckle, or the knob of a coated rod, you will obtain a spark. This operation may be repeated many times, without exciting the under plate.

Ques. Can you charge a Leyden jar in this way?

Ans. Yes, it has been done, and by a single excitation, so as to pierce a hole through a jar of glass.

Here is another kind of electrometer (Plate II. Fig. 18.) which is by far the most sensitive that has been yet invented; that is, it is capable of discovering the smallest quantities of electricity. A is a glass jar, B the cover of metal, to which are attached two pieces of gold leaf *x*, or two pith-balls suspended on threads: on the sides of the glass jar are two narrow strips of tin foil.

Charles. How is this instrument used?

Tutor. Any thing that is to be electrified is brought to the cover, which will cause the pieces of gold leaf, or pith-balls to diverge; and the sensibility of this instrument is so great, that the brush of a feather, the throwing of charcoal-powder, or dust, against the cap B, evince strong signs of electricity.

Ex. 5. Place on the cap B a little powder, or any other metallic cup, having some water

it : then take from the fire a live candle put it in the cup, and the electricity of va very admirably exhibited.

A thunder-cloud passing over this inst will cause the gold leaf to strike the s every flash of lightning.

Ex. 6. I will excite this stick of sealing wax and bring it to the cover B : you see how it causes the gold leaf to strike against the edge of the glass.

James. Are the slips of tin foil intended to carry away the electric fluid communicated to the objects presented to the cap A ?

Tutor. They are ; and by them the equilibrium is restored.

CONVERSATION XXXVIII.

Of Atmospheric Electricity.

Charles. You said yesterday, that the electrometer was affected by thunder and lightning : are lightning and electricity similar ?

Tutor. They are, undoubtedly, the same.

and that they are the same, was discovered by Dr. Franklin more than half a century ago.

James. How did he ascertain this fact?

Tutor. He was led to the theory from observing the power which uninsulated points have in drawing off the electricity from bodies. After having formed his system, he was waiting for the erection of a spire, in Philadelphia, to carry his views into execution, when it occurred to him that a boy's kite would answer his purpose better than a spire. He therefore prepared a kite, and having raised it, he tied to the end of the string a silken cord, by which the kite was completely insulated. At the junction of the two strings he fastened a key as a good conductor, in order to take sparks from it.

Charles. Did he obtain any sparks?

Tutor. One cloud, which appeared like a thunder-cloud, passed without any effect; shortly after, the loose threads of the hempen string stood erect, in the same manner as they would if the string had been hung on an electrified insulated conductor. He then presented his knuckle to the key, and obtained an evident spark. Others succeeded before the string was wet, but when the rain had wetted the string, it collected the electricity very plentifully :

—Led by the phosphor light, with daring tread,
Immortal Franklin sought the fiery bed ;
Where, nurs'd in night, incumbent tempest shrouds
The seeds of thunder in circumfluent clouds ;

Benig'd with iron points his airy cell,
And pierc'd the monster slumb'ring in the shell.

DARWIN.

James. Could I do so with our large kite?

Tutor. I hope you will not try to raise your kite during a thunder storm, because, without very great care, it may be attended with the most serious danger. Your kite is, however, quite large enough, being four feet high, and two feet wide: every thing depends on the string, which, according to Mr. Cavallo, who has made many experiments on the subject, should be made of two thin threads of twine, twisted with a copper thread. And to Mr. Cavallo's work on electricity, Vol. II. such persons as are desirous of raising kites, for electrical purposes, should be referred, in which they will find ample instruction.

Charles. How do the conductors, which I have seen fixed to various buildings, act in dispersing lightning?

Tutor. You know how easy it is to charge a Leyden jar: but if, when the machine is at work, a person hold a point of steel, or other metal, near the conductor, the greater part of the fluid will run away by that point instead of proceeding to the jar. Hence it was concluded that pointed rods would silently draw away the lightning from clouds passing over any building.

James. Is there not a particular method of fixing them?

Tutor. Yes: the metallic rod must reach from the ground or the nearest piece of water, to a foot or two above the building it is intended to protect, and the iron rod should come to a fine point. Some electricians recommend that the point should be of gold, to prevent its rusting.

Charles. What effects would be produced, if lightning should strike a building without a conductor?

Tutor. That may be best explained, by informing you of what happened, many years ago, to St. Bride's church. The lightning first struck the weathercock, from thence descending in its progress, it beat out a number of large stones at different heights, some of which fell upon the roof of the church, and did great damage to it. The mischief done to the steeple was so considerable, that eighty-five feet of it was obliged to be taken down.

James. The weathercock was probably made of iron, why did not that act as a conductor?

Tutor. Though that was made of iron, yet it was completely insulated by being fixed in stone, that had become dry by much hot and dry weather. When therefore the lightning had taken possession of the weathercock, by endeavouring to force its way to another conductor, it beat down whatever stood in its way.

Charles. The power of lightning must be very great.

Tutor. It is irresistible in its effects ; the following experiment will illustrate what I have been saying.

Ex. 1. *A* is a board (Plate VIII. Fig. 19.) representing the gable end of a house : it is fixed on another board *B* : *a b c d* is a square hole, to which a piece of wood is fitted ; *a d* represents a wire fixed diagonally on the wood *a b c d* ; *x b* terminated by a knob *x*, represents a weather-cock, and the wire *c x* is fixed to the board *A*.

It is evident that in the state in which it is drawn in the figure, there is an interruption in the conducting rod ; accordingly, if the chain *m* is connected with the outside of a Leyden phial, and then that phial is discharged through *x*, by bringing one part of the discharging rod to the knob of the Leyden phial, and the other to within an inch or two of *x*, the piece of wood *a b c d* will be thrown out with violence.

James. Are we to understand by this experiment, that if the wire *x b* had been continued to the chain, that the electric fluid would have run through it without disturbing the loose board ?

Tutor. **Ex. 2.** Just so ; for if the piece of wood be taken out, and the part *a* be put to the place *b*, then *d* will come to *c*, and the conducting rod will be complete, and continued from *x* through *b c* to *x*, and now the phial may be dis-

charged as often as you please, but the wood will remain in its place, because the electric fluid runs through the wire to z , and makes its way by the chain to the outside of the phial.

Charles. Then if x be supposed the weathercock of the church, the lightning having overcharged this, by its endeavours to reach another conductor, as c z , forced away the stone or stones represented by a b c d ?

Tutor. That is what I mean to convey to your minds by the first experiment; and the second shows very clearly that if an iron rod had gone from the weathercock to the ground, without interruption, it would have conducted away the electricity silently, and without doing any injury to the church.

James. How was it that all the stones were not beaten down?

Tutor. Because, in its passage downwards, it met with many other conductors. I will read part of what Dr. Watson says on this fact, who examined it very attentively:

“The lightning,” says he, “first took a weathercock, which was fixed at the top of the steeple, and was conducted without injuring the metal or any thing else, as low as where the large iron bar or spindle which supported it terminated; there the metallic communication ceasing, part of the lightning exploded, cracked and shattered the obelisk which terminated the spire of the steeple, in its whole diameter,

and threw off, at that place, several large pieces of Portland stone. Here it likewise removed a stone from its place, but not far enough to be thrown down. From thence the lightning seemed to have rushed upon two horizontal iron bars, which were placed within the building across each other. At the end of one of the iron bars, it exploded again, and threw off a considerable quantity of stone. Almost all the damage was done where the ends of the iron bars had been inserted into the stone, or placed under it; and in some places, its passage might be traced from one iron bar to another."

The thunder holds his black tremendous throne :
 From cloud to cloud the rending lightnings rage ;
 Till, in the furious elemental war
 Dissolv'd the whole precipitated mass
 Unbroken floods and solid torrents pours.

THOMSON.

CONVERSATION XXXIX.

On Atmospheric Electricity—Of Falling Stars—Of the Aurora Borealis—Of Water-spouts, and Whirlwinds—Of Earthquakes.

Charles. Does the air always contain electricity?

Tutor. Yes; and it is owing to the electricity of the atmosphere that we observe a number of curious and interesting phenomena, such as falling stars; the aurora borealis, or northern lights; the ignis fatuus, or Will-with-the-wisp.

James. I have frequently seen what people call falling stars, but I never knew that they were occasioned merely by electricity.

Tutor. These are seen chiefly in clear and calm weather: it is then that the electric fluid is probably not very strong, and passing through the air it becomes visible in particular parts of its passage, according to the conducting substances it may meet with. One of the most striking phenomena of this kind is recorded by Signior Beccaria.—As he was sitting with a friend in the open air, an hour after sun-set, they saw a falling, or, as it is sometimes called, shooting star, directing its course towards them, growing, apparently, larger and larger, till it disappeared not far from them, and, disappearing, it left their faces, hands, and clothes, with the earth and neighbouring objects, suddenly illuminated with a diffused and lambent light, attended with no noise at all.

Charles. But how did he know that this was only the effect of electricity?

Tutor. Because he had previously raised his kite, and found the air very much charged with electric matter: sometimes he saw it ad-

ancing to his kite like a falling star; sometimes he saw a kind of glory round it, which followed it as it changed its place.

James. Since lofty objects are exposed to effects of lightning, or the electric fluid, do the tall masts of ships run considerable risk of being struck by it?

Tutor. Certainly: we have many instances recorded of the mischief done to ships, of which is related in the Philosophical Transactions; it happened on board the *Montagu* on the 4th of November, 1748, in latitude 48° and $9^{\circ} 3'$ west longitude, about noon. One of the quarter-masters desired the captain to have the vessel to look to the windward, when he observed a large ball of blue fire, rolling serenely on the surface of the water, at the distance of three miles from them. It rose most perpendicular when it was within forty or fifty yards from the main-chains of the ship, then went off with an explosion, as if a loaded cannon had been fired at one time; it left so strong a smell of sulphur, that it seemed to contain nothing else. After the smoke had subsided, the main top-mast was shattered to pieces, and the mast itself was thrown quite down to the keel. Five men were killed, and one of them greatly burnt by the explosion.

Charles. Did it not seem to be a very large ball, to have produced such effects?

Tutor. Yes: the person who noticed it said it was as big as a mill-stone.

The aurora borealis is another electrical phenomenon: this is admitted without any hesitation, because electricians can readily imitate the appearance with their experiments.

James. It must be, I should think, on a very small scale.

Tutor. True: there is a glass tube about thirty inches long, and the diameter of it is about two inches; it is nearly exhausted of air, and capped on both ends with brass. I now connect these ends, by means of a chain, with the positive and negative part of a machine, and in a darkened room, you will see, when the machine is worked, all the appearances of the northern lights in the tube.

Charles. Why is it necessary nearly to exhaust the tube?

Tutor. Because the air, in its natural state, is a very bad conductor of the electric fluid; but when it is, perhaps, rendered some hundred times rarer than it usually is, the electric fluid starts from one cap to the other, with the greatest ease.

James. But we see the aurora borealis in the common air.

Tutor. We do so: it is, however, in the higher regions of the atmosphere, where the air is much rarer than it is near the surface of the earth. The experiment which you have just

seen accounts for the darting and undulating motion which takes place between the opposite parts of the heavens. The aurora borealis is the most beautiful and brilliant in countries at the high northern latitudes, as in Greenland and Iceland.

Charles. I remember the lines on this subject:

By dancing meteors then, that ceaseless shake
A waving blaze refracted o'er the heavens,
And vivid moons, and stars that keener play
With double lustre from the glossy waste,
Ev'n in the depth of polar night, they find
A wond'rous day; enough to light the chase,
Or guide their daring steps to Finland fairs.

Tutor. The aurora borealis that was seen in this country, on the 23d of October, in the year 1804, is deserving of notice. At seven in the evening, a luminous arch was seen from the centre of London, extending from one point on the horizon, about S. S. W. to another point on N. N. W. and passing the middle of the constellation of the Great Bear, which it, in a great measure, obscured. It appeared to consist of shining vapour, and to roll from the south towards the north. In about half an hour, its colour was changed; it then became vertical, and about nine o'clock it extended across the heavens from N. E. to S. W.; at intervals, the continuity of the luminous arch was broken, and there then darted from its south-west quarter

nds the zenith, strong flashes and streaks ight red, similar to what appears in the at- here, during a great fire in any part of the opolis. For several hours the atmosphere as light in the south-west as if the sun had ut half an hour; and the light in the north nbled the strong twilight which marks that of the horizon at midsummer. Thomson, king of the aurora borealis, and other me-, says—

Silent from the north,
A blaze of meteors shoots; ensweeping first
The lower skies, they all at once converge
High to the crown of heaven, and all at once
Relapsing quick, as quickly re-ascend,
And mix and thwart, extinguish and renew,
All æther coursing in a maze of light.

mes. How do you account, sir, for the -with-the-wisp, or Jack-a-lantern, that is to the ground where the air is thickest? *ator.* This is a meteor which seldom ap- s more than six feet above the ground; it ways about bogs and swampy places, and , in hot weather, emit what is called in- nable air, which is easily inflamed by the ric spark. These, therefore, as you shall in our chemical experiments, we can as ily imitate as the aurora borealis.—In some of Italy, meteors of this kind are frequent- ry large, and give a light equal to that of ch.

Water-spouts, which are sometimes seen at sea, are supposed to arise from the power of electricity.

Charles. I have heard of these, but I thought that water-spouts at sea, and whirlwinds and hurricanes by land, were produced solely by the force of the wind.

Tutor. The wind is, undoubtedly, one of the causes, but it will not account for every appearance connected with them. Water-spouts are often seen in calm weather, when the sea seems to boil, and send up a smoke under them, rising in a sort of hill towards the spout. A rumbling noise is often heard at the time of their appearance, which happens generally in those months that are peculiarly subject to thunder-storms, and they are commonly accompanied or followed by lightning. When these approach a ship, the sailors present and brandish their swords to disperse them, which seems to favour the conclusion, that they are electrical.

James. Do the swords act as conductors?

Tutor. They may, certainly; and it is known that by these pointed instruments, they have been effectually dispersed.

The analogy between the phenomena of water-spouts, and electricity, may be made visible by hanging a drop of water to a wire, communicating with the prime conductor, and placing a vessel of water under it. In these circumstances, the drop assumes all the various ap-

appearances of a water-spout, in its rise, form, and mode of disappearing.

Water-spouts, at sea, are undoubtedly very like whirlwinds and hurricanes by land. These sometimes tear up trees, throw down buildings, make caverns; and, in all the cases, they scatter the earth, bricks, stones, timber, &c. to a great distance in every direction. Dr. Franklin mentions a remarkable appearance, which occurred to Mr. Wilke, a considerable electrician. On the 20th of July, 1758, at three o'clock in the afternoon, he observed a great quantity of dust rising from the ground, and covering a field, and part of the town in which he then was. There was no wind, and the dust moved gently towards the east, where there appeared a great black cloud, which electrified his apparatus positively to a very high degree. This cloud went towards the west, the dust followed it, and continued to rise higher and higher, till it composed a thick pillar, in the form of a sugar loaf, and at length it seemed to be in contact with the cloud. At some distance from this, there came another great cloud, with a long stream of smaller ones, which electrified his apparatus negatively, and when they came near the positive cloud, a flash of lightning was seen to dart through the cloud of dust, upon which the negative clouds spread very much, and dissolved in rain, which presently cleared the atmosphere.

Charles. Is rain then an electrical phenomenon?

Tutor. The most enlightened and formed electricians reckon rain, hail, &c. among the effects produced by the fluid.

James. Do the negative and positive act in the same manner as the outside coatings of a charged Leyden jar?

Tutor. Thunder-clouds frequently do more than conduct or convey the electric fluid from one place to another.

Charles. Then they may be compared to a discharging-rod.

Tutor. And perhaps, like that, they tend to restore the equilibrium between places, one of which has too much, the other too little of the electric fluid. A lowering is not an uncommon appearance. A dark cloud is observed to attract other clouds, and when grown to a considerable size its lower surface swells in particular parts towards the earth. During the time that they are thus forming, flashes of lightning come from one part of it to the other, and often from the whole mass; and small clouds are moving rapidly beneath it. When a cloud has acquired a sufficient extent, it strikes the earth in two opposite places.

James. I wonder the discharge does

the earth, as the charge of a jar does any thing through which it passes.

Tutor. Every discharge of clouds through the earth may do this, though it is imperceptible to us.

Earthquakes are probably occasioned by various discharges of the electric fluid: they happen most frequently in dry and hot countries, which are subject to lightning, and other electric phenomena: they are even foretold by the electric coruscations, and other appearances in the air for some days preceding the event. Besides the shock of an earthquake is instantaneous to the greatest distances. Earthquakes are usually accompanied with rain, and sometimes by the most dreadful thunder-storms:

How greatly terrible, how dark and deep
The purposes of Heaven! At once o'erthrown,
White age and youth, the guilty and the just,
Oh, seemingly severe! promiscuous fall.
Reason, whose daring eye in vain explores
The fearful Providence, confused, subdued
To silence and amazement, with due praise
Acknowledges th' Almighty, and adores
His will uttering, wisest, justest, best.

MALLET.

ELECTRICITY.

CONVERSATION XL.

Medical Electricity.

Tutor. If you stand on the stool with glass legs, and hold the chain from the conductor while I work the machine a few minutes, your pulse will be increased; that is, it will beat more frequently than it did before. From this circumstance physicians have applied electricity to the cure of many disorders: in some of which their endeavours have been unavailing, in others the success has been very complete.

Charles. Did they do nothing more than this?

Tutor. Yes, in some cases they took sparks from their patients, in others they gave them shocks.

James. This would be no pleasant method of cure, if the shocks were strong.

Tutor. You know, by means of Lane's electrometer, described in our thirty-fourth Conversation, (Plate VII. Fig. 10.) the shock may be given as slightly as you please.

Charles. But how are shocks conveyed through any part of the body?

Tutor. There are machines and apparatus made purposely for medical purposes, but every one may be answered by the instrument just

referred to. Suppose the electrometer to be fixed to a Leyden phial, and the knob at A to touch the conductor, and the knob B to be so far off as you mean the shocks to be weak or strong; a chain or wire of sufficient length is to be fixed to the ring C of the electrometer, and another wire or chain to the outside coating; the other ends of these two wires are to be fastened to the two knobs of the discharging-rod.

James. What next is to be done, if I wish to electrify my knee for instance?

Tutor. All you have to do is to bring the balls of the discharging-rod close to your knee, one on the one side, and the other on the opposite side.

Charles. And at every discharge of the Leyden jar, the superabundant electricity from within will pass from the knob at A to the knob B, and will pass through the wire and the knee, in its way to the outside of the jar, to restore to both sides an equilibrium.

James. But if it happen that a part of the body, as an arm, is to be electrified, how is it to be done, because in that case I cannot use both my hands in conducting the wires?

Tutor. Then you may seek the assistance of a friend, who will by means of two instruments called *directors*, be able to conduct the fluid to any part of the body whatever.

Charles. What are directors?

Tutor. A director consists of a knobbed bras

If I feel rheumatic pains between my elbow and wrist, and a person hold one director at the elbow, and another about the wrist, the electric fluid will pass through, and probably will be useful in removing the complaint.

James. Is it necessary to stand on the footed stool to have this operation performed?

Tutor. By no means: when shocks are ministered, the person who receives them may stand as he pleases, either on the stool or on the ground; the electric fluid taking the easiest passage, will always find the other director, which leads to the jar of the jar.

Charles. Is it necessary to make the skin bare?

■

Tutor. Not in the case of shocks. un

ralytic disorders ; in contractions of the nerves ; in sprains, and in many other cases ; but great attention is necessary in regulating the force of the shock, because, instead of advantage ; mischief may occur, if it be too violent.

Charles. Is there less danger with sparks ?

Tutor. Yes : for unless it be in very tender parts, as the eye, there is no great risk in taking sparks : and they have proved very effectual in removing many complaints.

The celebrated Mr. Ferguson was seized at Bristol, with a violent sore throat, so as to prevent him from swallowing any thing : he caused sparks to be taken from the part affected, and in the course of an hour he could eat and drink without pain.

This is an excellent method in cases of deafness, ear-ache, tooth-ache, swellings inside the mouth, &c.

James. Would not strong sparks injure the ear ?

Tutor. They might ; and therefore the electric fluid is usually drawn with a pointed piece of wood, to which it comes in a stream, or when sparks are taken, a very small brass ball is used, because, in proportion to the size of the ball, is the size of the spark.

CONVERSATION XLI.

al Electricity : of the Torpedo : of the Gymnotus Electricus, and of the Silurus Electricus.

or. There are three kinds of fish which have been discovered that are possessed of the singular property of giving shocks very similar to those experienced by means of the Leyden

Charles. I should like much to see them : are they easily obtained ?

Tutor. No, they are not : they are called the Torpedo, the *gymnotus electricus*, and the *silurus electricus*.

James. Are they all of the same species ?

Tutor. No : the torpedo is a flat fish, seldom more than six inches long, and is common in various parts of the sea coast of Europe. The electric organs of this fish are placed on each side of the gills, where they fill up the whole thickness of the animal, from the lower to the upper surface, and are covered by the common skin of the body.

Charles. Can you lay hold of the fish by any other part of the body with impunity ?

Tutor. Not altogether so : for if it be touched with one hand, it generally communicates a

very slight shock ; but if it be touched with both hands at the same time, one being applied to the under, and the other to the upper surface of the body, a shock will be received similar to that which is occasioned by the Leyden jar.

James. Will not the shock be felt if both hands be put on one of the electrical organs at the same time ?

Tutor. No : and this shows that the upper and lower surfaces of the electric organs are in opposite states of electricity, answering to the positive and negative sides of a Leyden phial.

Charles. Are the same substances conductors of the electric power of the torpedo, by which artificial electricity is conducted ?

Tutor. Yes, they are : and if the fish, instead of being touched by the hands, be touched by conducting substances, as metals, the shock will be communicated through them. The circuit may also be formed by several persons joining hands, and the shock will be felt by them all at the same time. But the shock will not pass where there is the smallest interruption ; it will not even be conducted through a chain.

James. Can you get sparks from it ?

Tutor. No spark was ever obtained from the torpedo, nor could electric repulsion and attraction be produced by it.

Charles. Is it known how the power is accumulated ?

Tutor. It seems to depend on the will of the

animal, for each effort is accompanied with a depression of its eyes, and it probably makes use of it as a means of self-defence.

James. Is this the case also with the other electrical fishes?

Tutor. The *gymnotus* possesses all the electric properties of the torpedo, but in a very superior degree. This fish has been called the electrical eel, on account of its resemblance to the common eel. It is found in the large rivers of South America.

Charles. Are these fishes able to injure others by this power?

Tutor. If small fishes are put into the water in which the *gymnotus* is kept, it will first stun or perhaps kill them, and if the animal be hungry, it will then devour them. But fishes stunned by the *gymnotus* may be recovered, by being speedily removed into another vessel of water.

The *gymnotus* is said to be possessed of a new kind of sense, by which it knows whether bodies, which are brought near him, are conductors or not.

Charles. Then it possesses the same knowledge by instinct which philosophers have gained by experiment.

Tutor. True: the following experiment, among others, is very decisive on this point.

Ex. The extremities of two wires were dipped into the water of the vessel in which the

animal was kept; they were then bent, extended a great way, and terminated in two separate glasses full of water. These wires, being supported by non-conductors, at a considerable distance from each other, the circuit was incomplete: but if a person put the fingers of both hands into the glasses in which the wires terminated, then the circuit was complete. While the circuit was incomplete, the fish never went near the extremities of the wires, as if desirous of giving the shock; but the moment the circuit was completed, either by a person, or any other conductor, the gymnotus immediately went towards the wires, and gave the shock, though the completion of the circuit was out of his sight.

James. How do they catch these kind of fish; the men would, probably, let them go on receiving the shock?

Tutor. In this way the property was, perhaps, first discovered. The gymnotus, as well as the others, may be touched, without any risk of the shock, with wax or with glass; but if it be touched with the naked finger, or with a metal, or a gold ring, the shock is felt up the arm.

Charles. Does the *silurus electricus* produce the same effects as the others?

Tutor. This fish is found in some rivers in Africa, and it is known to possess the property of giving the shock, but no other particulars have been detailed respecting it.

whence it cannot be taken, except when
toxicated. It cannot be touched with the
hand or with a stick, without feeling a terrible
pain. If trod upon with shoes, the legs and
feet are affected in a similar manner.

CONVERSATION XLII.

General Summary of Electricity, with Experiments.

Tutor. You now understand what elec-

Tutor. When a body is possessed of more, or retains less, than its natural share, it is said to be *charged* or electrified.

Charles. If it possess more than its natural share, it is said to be *positively* electrified; but if it contain less than its natural share, it is said to be *negatively* electrified.

Tutor. Does it not sometimes happen, that the same substance is both positively and negatively electrified at the same time?

James. Yes: the Leyden jar is a striking instance of this, in which, if the inside contain more than its natural share, the outside will contain less than its natural quantity.

Tutor. What is the distinction between conductors and non-conductors of electricity?

Charles. The electric fluid passes freely through the *former*, but the *latter* oppose its passage.

Tutor. You know that electricity is excited in the greatest quantities, by the friction of conducting and non-conducting substances against each other.

Ex. Rub two pieces of sealing-wax, or two pieces of glass together, and only a very small portion of electricity can be obtained; therefore the rubber of a machine should be a conducting substance, and not insulated.

Every electrical machine, with an insulated rubber, will act in three different ways; the rubber will produce *negative* electricity: the

conductor will give out *positive* electricity: and it will communicate both powers at once to any person or substance placed between two directors connected with them.

James. How does the rubber produce negative electricity?

Tutor. If you stand on a stool with glass legs, or upon any other non-conducting substance, and lay hold of the rubber, or a chain that communicates with it, the working the machine will take away from you a quantity of your natural electricity, therefore you will be negatively electrified.

Charles. Will this appear by the nature of the electric fluid, if I hold in my hand a steel point, as a needle?

Tutor. If you, standing on a non-conducting substance, are connected with the rubber, and your brother, in a similar situation, connected with the conductor, hold points in your hands, and I, while I stand on the ground, first present a brass ball, or other substance, to the needle in your hand, and then to that in his hand, the appearance of the fluid will be different in both cases; to the needle in your hand it will appear like a star, but to that in your brother's it will be rather in the form of a brush.—What will happen if you bring two bodies near to one another, that are both electrified?

James. If they are both positively or both

negatively electrified, they will repel each other but if one is negative and the other positive they will attract one another till they touch, and the equilibrium is again restored.

Tutor. If a body containing only its natural share of electricity, be brought near to another that is electrified, what will be the consequence?

Charles. A quantity of electricity will force itself through the air in the form of a spark.

Tutor. When two bodies approach each other, one electrified positively and the other negatively, the superabundant electricity rushes violently from one to the other to restore the equilibrium. What will happen if your body, or any part of it, form part of the circuit?

James. It will produce an electric shock, and if, instead of one person alone; many join hands, and form a part of the circuit, they will all receive a shock at one and the same instant.

Tutor. If I throw a larger quantity of electricity than its natural share on one side of a piece of glass, what will happen to the other side?

Charles. The other side will become negatively electrified: that is, it will have as much less than its natural share, as the other has more than its natural share.

Tutor. Does electricity, communicated to glass, spread over the whole surface?

James. No; glass being an excellent non-conductor, the electric fluid will be confined to the part on which it is thrown: and for this

reason, and in order to apply it to the whole surface, the glass is covered with tin foil, which is called a coating.

Tutor. And if a conducting communication be made between both sides of the glass, what takes place then?

Charles. A discharge; and this happens whether the glass be flat, or in any other form.

Tutor. What do you call a cylindrical glass vessel thus coated for electrical purposes?

James. A Leyden jar; and when the inside and also the outside, of several of these jars are connected, it is called an electrical battery.

Tutor. Electricity, in this form, is capable of producing the most powerful effects, such as melting metals, firing spirits, and other inflammable substances.—What effect has metal points on electricity?

Charles. They discharge it silently, and hence their great utility in defending buildings from the dire effects of lightning.—Pray, what is thunder?

Tutor. As lightning appears to be the rapid motion of vast masses of electric matter, thunder is the noise produced by the motion of lightning: and when electricity passes through the higher parts of the atmosphere, where the air is very much rarefied, it constitutes the Aurora borealis.

Ex. If two sharp pointed wires be (Plate VIII. Fig. 30:) with the four e

right angles, but pointing different ways, and they be made to turn upon a wire fixed on the conductor, the moment it is electrified, a flame will be seen at the points *a b c d* ; the wire will begin to turn round in the direction opposite to that to which the points are turned, and the motion will become very rapid.

If the figures of horses, cut in paper, be fastened upon these wires, the horses will seem to pursue one another, and this is called the electrical horse-race. Of course, upon this principle, many other amusing and very beautiful experiments may be made : and upon this principle several electrical orreries have been contrived, showing the motions of the earth and moon, and the earth and planets round the sun.

James. How do you account for this ?

Tutor. Fix a sharp pointed wire into the end of the large conductor, and hold your hand near it :—no sparks will ensue ; but a cold blast will come from the point which will turn any light mills, wheels, &c.

GALVANISM,

OR

VOLTAISM.

CONVERSATION XLIII.

Galvanism ; its Origin ; Experiments.—Of the decomposition of Water:

TUTOR. It has been observed as long as I remember, and probably before I was born, that porter, when taken from a pewter pot, had a superior flavour than when drunk out of a glass, or china.

Charles. Yes ; I have often heard my uncle say so ; but what is the reason of it ?

Tutor. Admitting the fact, which is, I believe, generally allowed by those who are much accustomed to that beverage ; it is now explained upon the principles of *Galvanism*.

James. Is Galvanism another branch of science ? is there a Galvanic fluid as well as an electric fluid ?

Tutor. Of the existence of the electric fluid we now have no doubt ; the science of electricity took its name from *electron*, the Greek word for amber, because amber was one of the first substances observed to produce, by rubbing, the effects of attraction and repulsion. Galvanism derives its name from Dr. Galvani,
VOL. III.—X

who first reported to the philosophical was experiments on which the science is founded. *Charles.* Pray how was he led to make experiments?

Tutor. Galvani, a professor of anatomy at Bologna, was one evening making some electrical experiments, and on the table where the machine stood, were some frogs skinned. An accident one of the company touching the main nerve of a frog, at the same moment he took a considerable spark from the conductor of the electrical machine, and the muscles of the frog were thrown into strong convulsions. These, which were observed by Galvani's wife, led the professor to a number of experiments, but as they cannot be repeated without much cruelty to living animals, I will not enter into a detail of them.

James. Were not the frogs dead which led to the discovery?

Tutor. Yes, they were: but the professor afterwards made many experiments upon living ones, whence he found that the convulsions as they are usually called, the contractions produced on the frog, may be excited with the aid of any apparent electricity, merely making a communication between the conductor and the muscles with substances that are good conductors of electricity.

Charles. Which are the best conducting substances?

Tutor. All the metals: but zinc and silver or zinc and copper, produce the greatest muscular contractions.

Charles. Are these experiments peculiar to frogs?

Tutor. No; they have been successfully made on almost all kinds of animals from the ox downwards to the fly. And hence it was at first concluded that there was an electricity peculiar to animals.

James. You have already shown that the electric fluid exists in our bodies, and may be taken from them, independently of that which causes the contractions.

Tutor. I will show you an experiment on this subject:—here is a thin piece of zinc which is a sort of metallic substance, but not what is denominated a perfect metal: lay it under your tongue, and lay this half-crown upon the tongue; do you taste any thing very peculiar in the metals?

James. No, nothing at all.

Tutor. Put them in the same position again and now bring the edges of the two metals into contact, while the other parts touch the under and upper surfaces of the tongue.

James. Now they excite a very disagreeable taste, something like copperas.

Tutor. Instead of the half-crown, try the experiment with a guinea, or with a piece of charcoal.

Charles. I perceive the same kind of which James described. How do you explain the fact?

Tutor. Some philosophers maintain the principle of Galvanism and electricity the same: and that the former is the evolution of the electric fluid from conducting bodies, disengaged by a chemical process; the latter is the same thing made apparent to the senses by non-conducting bodies.

James. All metals, as we have seen, are conducting substances; of course, the zinc, the guinea, and the half-crown, are conductors.

Tutor. Yes, and so are the tongue and the saliva; and it is probable, that by the position of some small particles of the metal, the sharp taste is excited.

Charles. What do you mean by decomposition of the saliva?

Tutor. We shall, in our chemistry, see that water is capable of being decomposed, is, separated into two gases, called hydrogen and oxygen.

James. Is saliva capable of being decomposed?

Tutor. Certainly, because a great quantity may be supposed to be water: and this combines with the metal, while the hydrogen escapes, and excites the taste on the tongue.

Charles. The disagreeable taste on the tongue cannot be disputed, but there is no

change on the zinc or the half-crown, which there ought to be if a new substance, as the oxygen, has entered into the combination.

Tutor. The change is, perhaps, too small to be perceived in this experiment: but in others on a larger scale, it will be very evident to the sight, by the *oxidation* of the metals.

James. Here is another strange word. I do not know what is meant by oxidation.

Tutor. The iron bars fixed before the window were clean and almost bright when placed there last summer.

James. But not being painted, they are become quite rusty.

Tutor. Now, in chemical language, the iron is said to be oxidated instead of rusty: and the earthy substance that may be scraped from them, used to be called the *calx* of iron; but it is, by modern chemistry, denominated the *oxide* of iron.

When mercury loses its fine brightness by being long exposed to the air, the dulness is occasioned by oxidation, that is, the same effect is produced by the air on the mercury, as it was on the iron. I will give you another instance. I will melt some lead in this ladle, you see a scum is speedily formed. I take it away, and another will arise, and so perpetually till the whole lead is thus transformed into an apparently different substance: this is called the *oxide* of lead.

CONVERSATION XLIV.

Galvanic Light and Shocks.

Charles. We had a *taste* of the Galvanic yesterday, is there no way of seeing it?

Tutor. Put this piece of zinc between upper lip and the gums, as high as you and then lay a half-crown, or guinea, upon tongue, and when so situated, bring the two into contact.

Charles. I thought I saw a faint flash of

Tutor. I dare say you did, it was for purpose I bade you make the experiment may be done in another way; by putting piece of silver up one of the nostrils, a zinc on the upper part of the tongue, and bringing the metals in contact, the same will be produced.

James. By continuing the contact of metals, the appearance of light does main.

Tutor. No, it is visible only at the moment of making the contact. You may, if you try the experiment with great attention, put a slip of tin foil over the ball of one finger, hold a tea-spoon in your mouth, and the communication between the spoon

tin a faint light will be visible. These experiments are best performed in the dark.

Charles. Is there no means of making experiments on a large scale?

Tutor. Yes, we have Galvanic, or, as they ought to be denominated, *Voltaic*, from Volta the inventor of them, batteries, as well as electrical batteries. Here is one of them. (Plate VIII. Fig. 20.) It consists of a number of pieces of silver, zinc, and flannel cloth, of equal sizes; and they are thus arranged, a piece of zinc, a piece of silver, a piece of cloth moistened with a solution of salt in water, and so on till the pile is completed. To prevent the pieces from falling, they are supported on the sides by three rods of glass stuck into a piece of wood, and down these rods slides another piece of wood which keeps all the pieces in close contact.

James. How do you make use of this instrument?

Tutor. Touch the lower piece of metal with one hand, and the upper one with the other.

James. I felt an electric shock.

Tutor. And you may take as many as you

* Galvani's discoveries were the result of mere accident and even but trifling, in comparison of those made by Volta a celebrated Italian, who improved the few hints before him into an important body of science: hence the term Voltaic will shortly, without doubt, supersede that of Galvanism.

lete; with your hands make a communication between the two end cells.

Charles. I felt a strong shock.

Tutor. Wet your hands, and join your left with James's right, then put your right hand into one end cell, and let James put his left into the opposite one.

James. We both felt the shock like an electric shock, but not so severe.

Tutor. Several persons may receive the shock together, by joining hands, if their hands are well moistened with water. The strength of the shock is much diminished by passing through so long a circuit. The shock from a battery, consisting of fifty or sixty pairs of zinc and silver, or zinc and copper, may be felt as high as the elbows. And if five or six such batteries be united with metal cramps, the combined force of the shock would be such that few would willingly take it a second time.

Charles. What are the wires for at each end of the trough?

Tutor. With these, a variety of experiments may be made upon combustible bodies. I will show you one with gunpowder, but I must have recourse to four troughs, united by cramps, or to one much larger than this.

Towards the ends of the wires are two pieces of glass tubes, these are for the operator to hold by, while he directs the wires. Suppose now four or more troughs united, and the wire

to be at the two extremities, I put some gunpowder on a piece of flat glass, and then holding the wires by the glass tubes, I bring the ends of them to the gunpowder, and just before they touch, the gunpowder will be inflamed.

Instead of gunpowder, gold and silver leaf may be burnt in this way: ether, spirits of wine, and other inflammable substances, are easily fired by the Voltaic battery; it will consume even small metallic wires.

Copper or brass leaf, commonly called Dutch gold, burns with a beautiful green light, silver with a pale blue light, and gold with a yellowish green light.

James. Will the battery continue to act any great length of time?

Tutor. The action of all these kinds of batteries is the strongest, when they are first filled with the fluid; and it declines in proportion as the metals are oxidated, or the fluid loses its power. Of course, after a certain time, the fluid must be changed and the metals cleaned, either with sand, or by immersing them a short time in diluted muriatic acid. The best fluid for filling the cells with, is water mixed with one-tenth of nitrous acid. Care must always be taken to wipe quite dry the edges of the plates, to prevent a communication between the cells: and it will be found, that the energy of the battery is in proportion to the rapidity with which the zinc is oxidated.

CONVERSATION XLV.

ic Conductors—Circles—Tables—Experiments.

Mr. You know that *conductors* of the electric fluid differ from each other in their conducting power.

Mrs. Yes, the metals were the most perfect conductors, then charcoal, afterwards water and other fluids. See p. 157.

Mr. In Voltaism we call the former *dry perfect* conductors, these are the first class : the latter, or second class, *imperfect* conductors : rendering the Voltaic power sensible, the combination must consist of three conductors of the different classes.

Mrs. Do you mean two of the first class, and one of the second ?

Mr. When two of these bodies are of the first class, and one is of the second, the combination is said to be of the *first order*.

Mrs. The large battery which you used in the experiment was of the *first order* then, because it consisted of two metals, viz. zinc and silver, and the fluid.

Mr. This is called a *simple Voltaic circle*, when the two metals touched each other in some points,

and at other points they were connected by the fluid which was of the different class.

James. Will you give us an example of the second order?

Tutor. When a person drinks porter from a pewter mug, the moisture of his under lip is one conductor of the second class, the porter is the other, and the metal is the third body, or conductor of the first class.

The discoloration of a silver spoon, in the act of eating eggs, is a Voltaic operation. A spoon merely immersed in the egg undergoes no discoloration, it is the act of eating that produces the change. This is a Voltaic combination of the second order, the fluid egg, and the saliva, are substances of the second class of conductors, and the silver of the first class.

Charles. Which are the most powerful Voltaic circles?

Tutor. They are those of the first order, where two solids of different degrees of oxidability are combined with a fluid capable of oxidating, at least, one of the solids. Thus gold, silver, and water, do not form an active Voltaic circle, but it will become active if a little nitric acid, or any fluid decomposable by silver, be mixed with the water. An active Voltaic circle is formed of zinc, silver, and water, because the zinc is oxidated by water. But a little nitric acid, added to the water, renders the combination still more active, as the acid acts upon the silver and the zinc.

st powerful Voltaic combinations of order are, where two conductors of class have different chemical actions ductors of the first class, at the same act upon each other. Thus copper, lead, with a solution of an alkaline and diluted nitrous acid, form a very aic circle. Hence the following

I will now show you another experiment which is to be made with the assistance of the great battery. (Fig. 22.) *A B* (Plate VIII. Fig. 23.) exhibits a glass tube, filled with distilled water, and having a cork at each end. *A* and *B* are two pieces of brass wire, which are brought to within an inch or two of one another in the tube, and the other ends are carried to the battery, viz. *A* to what is called the positive end, and *B* to the negative end.

James. You have then positive and negative Voltaism, as well as electricity?

Tutor. Yes, and if the circuit be interrupted, the process will not go on. But if all things be as I have just described, you will see a constant stream of bubbles of gas proceed from the wire *B*, which will ascend to the upper part of the tube. This gas is found to be hydrogen or inflammable air.

Charles. How is that ascertained?

By bringing a candle close to the when I take out the cork A, the gas immediately inflame. The bubbles which from the wire A are oxygen or pure air, mulate and stick about the sides of the

How is this experiment explained?

It is believed that the water is decomposed into hydrogen and oxygen: oxygen is separated from the water by connected with the negative extremity, oxygen unites with and oxidates the connected with the positive end of the

connect the positive end of the battery over wire, and the negative with the when the hydrogen proceeds from the e, and the lower wire is oxidated.

of gold or platina be used which are ble, then a stream of gas issues from ch may be collected, and will be found ixture of hydrogen and oxygen.

. Are there no means of collecting ls separately?

Yes, instead of making use of the e extremities of the wires, which pro- a the battery, be immersed in water, tance of an inch from each other, then ver each a glass vessel, inverted and ater (Plate VIII. Fig. 24.) and differ- of gas will be found in the two glasses.

It is known that hydrogen gas reduces the oxides of metals, that is, restores them to their metallic state. If, therefore, the tube (Fig. 23.) be filled with a solution of acetite of lead,* in distilled water, and a communication is made with the battery, no gas is *perceived* to issue from the wire, which proceeds from the *negative* end of the battery, but in a few minutes, beautiful metallic needles may be seen on the extremity of this wire.

James. Is this the lead separated from the fluid?

Tutor. It is; and you perceive it is in a perfect metallic state, and very brilliant. Let the operation proceed, and these needles will assume the form of fern, or some other vegetable substance.

The spark from a Voltaic† battery acts with wonderful activity upon all inflammable bodies, and experiments made in a dark room, upon gunpowder, charcoal, metallic wire, and metallic leaves, &c. may be made very amusing.

* Acetite of lead is a solution of lead in acetous acid.

† Mr. Davy has, by means of a very powerful battery, been enabled to decompose the alkalies, many of the earths, sulphur, phosphorus, and charcoal; also the boracic, fluoric, and muriatic acids. His first experiments were on pot-ash and soda, which, instead of being simple substances, are found to consist of certain metallic substances and oxygen. See Dialogues on Chemistry.

CONVERSATION XLVI.

Miscellaneous Experiments.

r. The discoveries of Galvani were made
ally with dead frogs; from his experi-
and many others that have been made
is time, it appears that the *nerves of ani-*
may be affected by smaller quantities of
ity, than any other substances with which
acquainted. Hence limbs of animals,
y prepared, have been much employed
obtaining the Voltaic electricity.

les. What is the method of preparation?

r. I have been cautious in mentioning
ments on animals, lest they should lead
trifle with their feelings: I must, how-
render the subject more complete, tell
at has been done.

muscles of a frog lately dead, and skin-
ay be brought into action by means of
all quantities of common electricity.

e leg of a frog recently dead be *prepared*,
, separated from the rest of the body,
a small portion of the spine attached to
so situated that a little electricity may
rough it, the leg will be instantly affect-
a kind of spasmodic contraction, some-

detached from the surrounding parts, coverings be removed from over the which depend on that nerve; and if a metal, as a wire, touch the nerve with tremity, and the muscle with the other, will be convulsed.

Charles. Is it necessary that the connection between the nerve and the muscle be made with a conducting substance?

Tutor. Yes, it is: for if sealing-wax &c. be used, instead of metals, no motion will be produced.

If part of a nerve of a *prepared* limb be laid up in a piece of tin foil, or be laid on of zinc, and a piece of silver be laid on end upon the muscle, and with the other end on tin or zinc, the motion of the limb will

rich the limb is not. If I now form a communication between the water in the two glassy means of silver, as a pair of tea-tongs; put the fingers of one hand into the water in the glass that contains the leg, and hold a piece of silver in the other, so as to touch the end of the nerves with it, the limb will be immediately excited, and sometimes when the experiment is well made, the leg will even pull out of the glass.

Ques. It is very surprising that such kind of contractions should be produced in dead animals.

Ans. They may be excited also in living animals: if a living frog be placed on a plate of zinc having a slip of tin foil upon its back, a communication be made between the zinc and tin foil, by a piece of metal, as silver, the same kind of contractions will take place.

Ques. Can this experiment be made without injury to the animal?

Ans. Yes, and so may the following:—I take a live flounder and dry it with a cloth, and put it in a pewter plate, or upon a large sheet of tin foil, and place a piece of silver on its back; I now make a communication between the metals with any conducting substance, and see the contractions, and the fish's uneasiness.

The fish may now be replaced in water. I place this leech on a crown piece, and then, endeavour to move away, let it touch a piece of zinc with its mouth, and you will see

VOLTAISM.

recoil, as if in great pain : the same
be done with a worm.

ieved that all animals, whether small
may be affected in some such manner
sm, though in different degrees.

nbs of people, while undergoing the
of amputation, have been convulsed
pplication of the instruments, an effect
easily explained by Voltaism.

e knowledge already obtained in this
the following facts are readily ex-

mercury retains its metallic splendour
a long time ; but its amalgam with any
metal is soon tarnished or oxidated.

cient inscriptions engraved upon pure lead,
reserved to this day, whereas some metals
osed of lead and tin, of no great antiquity,
ery much corroded.

orks of metals, whose parts are soldered
ther by the interposition of other metals,
oxidate about the parts where the differ-
metals are joined. And there are persons
o profess to find out seams in brass and cop-
vessels by the tongue, which the eye cannot
cover ; and they can, by this means, distin-
sh the base mixtures which abound in gold
silver trinkets.

When the copper sheeting of ships is fasten-
on by means of iron nails, those nails, but

cularly the copper, are very quickly corroded about the place of contact.

A piece of zinc may be kept in water a long time without scarcely oxidating at all; but oxidation takes place very soon if a piece of copper touch the zinc, while standing in the water.

If a cup made of zinc or tin be filled with water, and placed upon a silver waiter, and the tip of the tongue be applied to the water, it will be found to be insipid; but if the waiter be held in the hand, which is well moistened with water, and the tongue applied as before, an acid taste will be perceived.

Ques. Is that owing to the circuit being completed by the wet hand?

Ans. It is: another experiment of a similar kind is the following: If a tin basin be filled with soap-suds, lime-water, or a strong solution of any acid, and then the basin be held in both hands, moistened with pure water, while the tongue is applied to the fluid in the basin, an *acid* taste will be sensibly perceived, though the liquor is insipid.

From this short account of Voltaism, it may be inferred:—

1) That it appears to be only another mode of citing electricity.

2) Voltaic electricity is produced by the chemical action of bodies upon each other.

stances.

(6.) Voltaic electricity is conducted same substances as common electricity.

(7.) When it is made to pass thr animal, it produces a sensation resemb electrical shock.

(8.) The electricity produced by the and electrical eel, is very similar to V

Feathers, electrified, their appearance, iii. 172.

Fire Engines, described, and the principle of them explained, ii. 130.

Fish, how they swim, ii. 139. Air-vessel of, the uses, ii. 140. Electrical, iii. 256.

- Flannel**, a conductor of sound, ii. 188.
- Blea**, circulation of the blood of a, i. 19.
- Flood-gates**, why made very thick, ii. 56.
- Fluids and Solids**, how distinguished, ii. 26—28.
- Particles of, exceedingly small, ii. 12. Incapable of compression, ii. 14, 15.
- Fluids** press equally in all directions, ii. 19. Incompressible, ii. 21. Air, compression of, ib. Weight and pressure of, experiments on, ii. 24, 25. Lateral pressure of, ii. 30—34. Difference between the weight and pressure of, ii. 52. Motion of ii. 63, 64. Experiments on the light and heavy ii. 97—99. Specific gravity of, differs according to the degrees of heat and cold, ii. 102.
- Force**, centrifugal, what meant by, i. 65.
- Fountains**, the principle of, explained, ii. 61.
- Fountain**, artificial, ii. 176.
- Franklin**, Dr. his experiments, iii. 301. Discover that lightning and electricity are the same, iii 302.
- Friction**, rubbing. Must be allowed for in mechanics, i. 98.
- Frogs**, experiments on, iii. 242, 257.
- Fulcrum**, the prop or centre on which a lever turns. What meant by, i. 78.

G

- Galvani**, Dr. his discoveries, iii. 242. Experiments on frogs, ib. and 257.
- Galvanic batteries**, how formed, iii. 247, 248. Shock, iii. 249.

- Galvanism**, what it is, iii. 241. From what it derived its name, ib. And electricity the same, iii. ib. Made apparent to the senses, iii. 243. Positive and negative, iii. 254. Summary of, iii. 261.
- Garden engines**, described, ii. 131.
- Gas**, a kind of air. Hydrogen, how procured, iii. 255. How collected, ib.
- Gauge**, a measure.
- Geocentric place of a planet**, what meant by, i. 230. Longitude, ib.
- Globe**, the greater part of its surface water, ii. 215. A representation of the earth, i. 152.
- Glue**, for what used, i. 26.
- Gravity**, the tendency which bodies have to the centre of the earth. Centre of, what meant by, i. 47. How found, i. 48. Acts upon all bodies, i. 30. The law of, i. 31 and 37. Illustrated, i. 31, 32, and 37, 38.
- Gravitation**, attraction of, defined, i. 29. Instances of, i. 29. By this force bodies tend to the centre of the earth, i. 30.
- Gregory**, Pope, rectifies the Julian year, i. 192.
- Guinea**, specific gravity of, ii. 76.
- Gunpowder**, how fired, iii. 250.
- Gymnotus**, described, iii. 230.

H

- Hammer**, philosophical, ii. 82.
- Hampstead**, the fine prospect from, iii. 88.
- Harvest-moon**, explained, i. 213—219. Cause of; i. 217.

Heat, expands all bodies, i. 22. The cause of great, i. 175.

Height of any place, how found, i. 42, 43.

Heliocentric longitude, i. 230.

Herschel, the planet, when discovered, i. 237. Its magnitude, distance, &c. i. 238, 239.

Hiero's crown, cheat respecting, how detected, ii. 89, 90.

Hogshead, how burst, ii. 45.

Hop-wagons, dangerous to meet in an inclining road, i. 51.

Horizon, the boundary where the sky seems to touch the surface of the earth or sea. Sensible and rational, i. 162. To which we refer the rising and setting of the sun, i. 163.

Hydraulics, hydrostatic principles applied to mills, engines, pumps, &c.

Hydrometer, an instrument to measure the strength of spirits. Described, ii. 100—102. To what applied, ii. 103.

Hydrostatics, the origin of the term, ii. 9. The objects of, ii. 10.

Hydrostatical paradox, explained, ii. 34—40.

Hydrostatical bellows, described, and explained, ii. 41—46. Press, ii. 46, and 132—134. Fluids, pressure of in proportion to the perpendicular heights, ii. 42.

Hygrometer, an instrument by which the moisture of the air is measured. Its construction and use, ii. 263. Different kinds of, ii. 263—266.

I & J

Jack-a-lantern, iii. 219.

Immerse, to plunge in.

Impel, to drive on.

Incidence, line of, ii. 202.

Incompressible, not capable of being pressed into a smaller compass.

Inertia, of matter, its tendency to continue in the state in which it is.

Ingenhouz, Dr. referred to, i. 26. His character, ib.

Interstices, the hollow spaces between the particles of matter.

Iron, oxide of, iii. 245.

Jupiter, the planet, its magnitude; distance from the sun; the velocity of its motions, i. 231. The length of its days and nights, i. 232. Satellites i. 232.

Julius Caesar, the part he took in reforming the year, i. 190, 191.

L

Lateral, sidewise.

Latitude, of the planets, their distance from ecliptic. Parallels of, i. 173.

Lead, eleven times heavier than water, ii. 32. Lide of, iii. 244. Acetite of, iii. 256.

Leaf, gold, silver, &c. how burnt, iii. 250.

Leaks, in banks, how secured, ii. 57.

- Leap-year, what* meant by, i. 190. Rule for knowing, i. 191.
- Lenses, different* kinds described, iii. 33.
- Levels, construction* of, ii. 18. Use of, ii. 18, 19.
- Lever, a bar, crow, &c.* For what used, i. 79. Why called a mechanical power, i. 79. Of the *first* kind, what instruments referred to, i. 85. How to estimate its power, i. 86. Of the *second* kind, what instruments referred to, i. 86. Of the *third* kind, what instruments referred to, i. 87—89.
- Levers, how many* kinds, i. 79. Their properties illustrated, i. 80—83.
- Light, its great* velocity, how discovered, i. 232. and iii. 10, 11. Of what composed, iii. 9. Sun, subject to apparent diminution, iii. 10. The source of light to the planetary worlds, ib. Moves in straight lines, iii. 13, 14. Ray of, what meant by, iii. 15. Reflected and refracted, iii. 17—20. Its great advantages, iii. 49. A compounded body, iii. 51. Galvanic, how perceived, iii. 246—248.
- Lines, right, what* meant by, i. 11.
- London, how* supplied with water. Bridge, water-works at, ii. 63, 130.
- Long days, the* reason of, i. 174.

M

- Machine, electrical*, iii. 158. The most powerful, iii. 164.
- Magnet, described*, iii. 127. Its uses, iii. 128. Directive property, iii. 127. Artificial, iii. 128. Properties of, iii. 130.

- ets*, how to make, iii. 135.
etic attraction and repulsion, iii. 131.
es, reason why they roll to greater or less
 unces, i. 58.
er's compass, described, iii. 139. Variation
 ii. 140.
 the planet, its distance from the sun; its ve-
 y; its magnitude, &c. i. 227—230..
r, every substance with which we are ac-
 nt. How defined, i. 14. Definition illus-
 ed, i. 15. Capable of infinite division, i. 15.
 arkable instances of the minute division of,
 i—18.
nical powers, how many, and what they are,
 i.
*nic*s, importance of, i. 76. Power gained by
 n, ib.
ry, the planet, its situation, i. 219, and Ve-
 why called inferior planets, ib. Rarely seen,
 10. Its distance from the sun; its velocity;
 ize, &c. 221. 222.
s, some more sonorous than others, ii. 190.
scofe, its principle explained, iii. 110. Sin-
 iii. 112. How made, iii. 113. Compound,
 114. Solar, iii. 117.
rs, the different kinds, iii. 59.
ntum, the moving force of a body. What
 nt by, i. 33. Illustrated, i. 34, 35, and 73.
y, counterfeit, wrong to pass it, ii. 94.
i, what meant by, i. 194. Difference between
 periodical and synodical, i. 195.
, to what laws subject, i. 39. Its declination,
 38. Its southing, ib. Its distance from the

earth, i. 163. Probably inhabited, i. 199. Eclipses of, i. 200.

Moon and earth, motions of explained, i. 195. Shines with borrowed light, i. 195. The length of her diameter, i. 196. Phases of, explained, i. 196. Her rotation described, i. 197. Length of her day, ib. Length of her year, ib.

Motion, centre of, what it is, i. 74. Laws of, i. 56. Must be committed to memory, i. 63, 64; the first illustrated, i. 56—60, the second illustrated, i. 60. the third illustrated, i. 61—63.

Motions, circular, exist in nature, i. 64.

Muschenbroeck, M. describes the electric shock, iii. 183.

Musical instruments depend on the air for action, ii. 210.

N

Nadir, the point under our feet.

Nautical Almanac, its use, i. 133.

Needle of the mariner's compass. Dipping, iii. 140.

Nerves and muscles, how conductors of the Galvanic fluid, iii. 242.

New Style, when adopted, i. 192.

Newton, Sir Isaac, his experiments on electricity, iii. 149.

Ninkler, M. his description of the electrical shock, iii. 183.

O

ts, by what means visible, iii. 24. The image how painted on the eye, iii. 87.
ce, of the shape of an orange.
ue, dark.
, the path of a planet round the sun, or of a
on round its primary.
ation, what meant by the term, iii. 245.
e, the calx of a metal. What meant by the
m, iii. 245.

P

, Dr. his natural theology referred to, iii. 88.
n's digester described; i. 23. and ii. 236. Its
ts, ib. One burst, ii. 237.
er, Mr. his large burning glass, iii. 35.
ussion, a stroke. What meant by, i. 71.
omenon, an appearance in nature.
, Leyden, where discovered, iii. 182.
sophy, what it is, i. 10. Natural and experi-
ntal, the introduction to, not difficult, ib. Na-
al, the uses to which it is applied, i. 60.
sophical Transactions, referred to, iii. 216.
tower of, leans out of the perpendicular, i. 50.
e, inclined, explained, i. 100. Examples re-
cting the, i. 101—104. What instruments
errible to, i. 103.
ets, their number and names, i. 145. Charac-
s of, i. 137. Latitude of, i. 141. The order
VOL. III.—A a

of their motions, i. 145. How to find their distances, i. 226, 227.

Pneumatics, what, treated of under, ii. 137.

Points, cardinal, i. 124.

Pole-star, its use, i. 124.

Poles, apparently stationary, i. 165. At the, only one day and one night in the year, i. 182.

Press, hydrostatical, ii. 45, 46.

Priestley, Dr. his history of electricity referred to, iii. 150.

Price, Dr. referred to, i. 40.

Prism, the effect of, iii. 95.

Puddling, what meant by the term, ii. 57.

Pulley, how explained, i. 96. The single gives no advantage, ib. The moveable, i. 98.

Pump, principle of, ii. 123—128.

Pump, forcing, described, ii. 128.

Pyrometer, its construction and use, ii. 260.

R

Radiant-points, from whence rays of light flow in all directions.

Rainbow, the cause explained, iii. 94. Artificial, iii. 99. Curious ones described, iii. 99, &c.

Rain-gauge, its construction, ii. 266. How it is used, ii. 267.

Rain, an electrical phenomenon, iii. 222.

Rays, pencil of, what meant by, iii. 32. Parallel, definition of, ib.

Reflection, rebounding back. Its powers in apparently multiplying objects, i. 121. Line of, explained, ii. 202.

ction, inclining or bending out of its course.
power in apparently multiplying objects, i.

sion, driving away. What meant by, i. 27.
ances of, i. 27, 28.

tum, electrical, what meant by, iii. 188.

grade motion, by which the heavenly bodies
ear to go backwards.

berate, to beat back.

New, how it supplies London with water,
3. Reservoirs belonging to, ii. 64.

, banks of, must be very thick, ii. 57.

labouts, the principle of, i. 75.

S

, decomposed by Galvanism, iii. 244.

whatever has a sharp taste, and is soluble in
er.

ater, heavier than fresh, consequence of, to
aded vessel, ii. 104.

tes, moons.

, the planet, how known, i. 234. Its magni-
distance from the sun; the velocity of its
ons, i. 234, 235. Its satellites and rings, i.

The length of its day and night, i. 236.

an inclined plane wrapt round a cylinder.
principle explained, i. 107. Of what com-

d, i. 108. Examples of, i. 109. Used by
er-makers, i. 112. Its power estimated, ib.

, the hottest, i. 178.

INDEX AND GLOSSARY.

- variety of, on what depends, i. 171.
 how accounted for, i. 171, 172.
 produced, i. 178.
 damaged by lightning, iii. 216.
electricus, described, iii. 231.
 experiment with, iii. 243.
 the structure of, explained, ii. 110.
 the use of, ii. 110.
- S** *Smoke*, how they get at their master's run.
Smoke, reason of its ascent, ii. 181.
Smoke-jack, its principle, ii. 213.
Solar System, described, i. 142, 148.
Solder, for what used, i. 26.
Sound, conductors of, ii. 187, 188. How
 be heard, ii. 191. How fast it travels,
 Velocity of, applied to practical purposes,
 195.
- S** *Spark*, electrical, its nature, iii. 199. Gal-
 power, iii. 256.
- S** *Specific gravity*, what meant by, ii. 26. C
 explained and illustrated, ii. 65, 96. How
 ii. 67.
- S** *Spectacles*, their construction, uses, and
 kinds, iii. 90, 94.
- S** *Spirit*, rectified, what meant by, ii. 101, &
Springs, intermitting, explained, ii. 113.
- S** *St. Paul's*, whispering gallery of, principle
 ed, ii. 208.
- S** *Stars*, how to find the names of, i. 126, 127,
 marked on the globe with Greek char-
 129. Fixed, their apparent motion, i. 1
 not seen in the day, i. 166. Fixed, their
 i. 117, 118. May be distinguished, i. 120.

air immense distance, i. 185. Fixed, description of, i. 145, 247. Their uses, i. 248. Falling, what they are, iii. 310.

an engine, its use, ii. 221. When invented, ii. 2. Its structure, ii. 224. The application, ii. 1, 232. That of Messrs. Whitbread described, 233. Its power calculated, ib. Accidents occasioned by, ii. 235.

yard, a sort of lever, i. 82. Its advantages over pair of scales, i. 82.

ms, by what occasioned, ii. 218.

ion, no such principle in nature, ii. 153—157.

huret, alkaline, what, iii. 253.

mers, two in a year, in some places, i. 181.

and Clocks, seldom together, i. 140.

declination of, i. 137. Longitude of, i. 141. as not latitude, ib. Its magnitude, i. 143. Why appears so small, ib. Its distance from the earth, i. 144. Annual motion of, how observed, 168. Reasons for, i. 130. Nearer to the earth in winter than in summer, i. 177. A description of, i. 243, 244.

arming, theory of, ii. 105. How to be attained, Less natural to man than to other land animals, ii. 106.

age, its structure explained, ii. 150. Condensing one described, ii. 177.

T

es, Galvanic, iii. 253, 254.

gent, a straight line, touching the circumference of a circle in one point.

Tangible, capable of being felt or handled.

Tantalus's cup, ii. 111.

Taste, a disagreeable one, excited by the union of metals placed on and under the tongue, iii. 243.

How accounted for, iii. 244.

Telescope, refracting, explained, iii. 100. Night, iii. 151. Reflecting, explained, iii. 107. Dr. Herschel's, iii. 110.

Terms, technical, derived from the Greek language, ii. 9.

Thermometer, its construction and uses, ii. 250—254. Its scale, ii. 254. Wedgewood's, ii. 256. Reaumur's scale compared with Fahrenheit's, ii. 259. Heat, scale of, ii. 258.

Thunder, how produced, ii. 189.

Tides, the causes of, explained, i. 207—212. Two every 25 hours, i. 210. Different in different places, i. 211. When the highest happen, i. 212.

Time, equal and apparent, how distinguished, i. 183, 184. On what the difference depends, i. 184. Equation of, i. 140 and 183—189. Division of, i. 194.

Time and space, clear ideas of, necessary to be formed i. 75.

Torpedo, described, iii. 228.

Torricellian, experiment, ii. 148.

Transferrer, an instrument used in pneumatics.

Transit of Venus, her passage over the sun's face.

Trembling eel, noticed, iii. 232.

Triangle, what meant by, i. 13. Any two sides of greater than the third, i. 68.

Tropics, circles parallel to the equator.

phet, speaking, described, ii. 196—199. When
t used, ii. 198.

phets, for deaf persons, ii. 199.

, a pipe.

ght, the degree of light experienced between
setting, or rising, and dark night.

U & V

lation, swinging or vibrating.

um, a place void of air.

, a sort of trap door.

s, what meant by, ii. 124.

ables, how blanched, iii. 56.

ity, a term applied to motion. Accelerating,
at meant by, i. 41.

s, the planet, its distance from the sun; the
ocity of its motion; its magnitude, i. 223,

i. Why an evening and why a morning star,
25. Transit of, what meant by, i. 226.

er, its construction and use, ii. 241.

x, the top of any thing.

tion, the swinging motion of a pendulum.

z, the manner of, iii. 84.

ile, any light substance that easily evaporates.

ic batteries, iii. 247—248. Shock, iii. 247—

).

ism, iii. 247, &c.

W

Wall, leaning one, at Bridgnorth, i. 501.

Water, pure rain, the standard to compare other bodies with, ii. 69. Weighs the same every where, ib. Always deeper than it appears to be, ii. 107, and iii. 36. How raised from deep wells, ii. 131, 132. Formed of two gases, iii. 244. Decomposed, iii. 255.

Water-spouts, their cause, iii. 220. How dispersed, ib.

Weather, rules for judging of, ii. 270—272.

Wedge, a triangular piece of wood or metal, to cleave stone, &c. Its principle explained, i. 104. Its advantages in cleaving wood, i. 105. What instruments referred to, i. 106.

Well, how to find the depth of one, i. 43.

Wheel and axis, described, i. 91. For what purposes used, ib. Its power estimated, i. 92. How increased, i. 92. Explained on the principle of the lever, i. 95.

White, Mr. James, his invention of a crane, i. 95. His patent pulley, i. 99.

Wind, what it is, ii. 212. The cause of, ii. 213. Experiment on, ii. 213 and 217. Definition of, ii. 215. Its direction denominated, ib. The cause of its variableness in England, ii. 217. How to find its velocity, ii. 219. Table of, ii. 220.

Winds, how many kinds, and why so named, ii. 214.

Winter, why colder than the summer, i. 177.

Y

Year, its length, how measured, i. 190. Gregorian, what meant by, i. 192. The beginning of, changed from the 25th of March to the 1st of January, i. 193.

Z

Zenith, that point of the heavens over one's head.
Zinc, experiment with, iii. 243.
Zodiac, a belt in the heavens, sixteen degrees broad, through which the ecliptic runs. Signs of, i. 135.
Dr. Watts's lines on, i. 136.
